more than it concentrates the protonated cation form. The pH of the medium containing the local anesthetic influences drug activity by altering the relative percentage of the base and protonated forms. For example, in inflamed tissues the pH is lower than normal, and local anesthetics are more protonated than in normal tissue and thus penetrate the tissue relatively poorly (see later). The relationship between pK_a and the percentage of local anesthetic present in the cationic form is shown in Fig. 29.2. As described later, there are dual effects of pH on clinical effectiveness, depending on where the local anesthetic is injected and the importance of the base form for tissue penetration.

Anatomy of the Peripheral Nerve

Each peripheral nerve axon possesses its own cell membrane, the axolemma. Nonmyelinated nerves, such as autonomic postganglionic efferent and nociceptive afferent C fibers, contain many axons encased in a single Schwann cell sheath. In contrast, all large motor and sensory fibers are enclosed in many layers of myelin, which consists of the plasma membranes of specialized Schwann cells that wrap themselves around the axon during axonal outgrowth. Myelin greatly increases the speed of nerve conduction by insulating the axolemma from the surrounding conducting salt medium and forcing the “action current” generated by an impulse to flow through the axoplasm to the nodes of Ranvier, which are periodic interruptions in the myelin sheath where the active impulse is regenerated (Fig. 29.3). The Na^+ channels that serve generation and propagation of impulses are highly concentrated at the nodes of Ranvier of myelinated fibers[7a] but are distributed all along the axon of nonmyelinated fibers (see Fig. 29.3). A classification of peripheral nerves according to fiber size and physiologic properties is presented in Table 29.3. It is important to note that different fiber classes are not only distinguished by diameter and myelin thickness, but also by the structure of the neuronal membrane and ion channel composition.[6]

Each axon has its own connective tissue covering, the *endoneurium*. A typical peripheral nerve consists of several axon bundles, or fascicles. Each fascicle of many axons is encased by a second connective tissue layer, the epithelial-like *perineurium*, and the entire nerve is wrapped in a loose outer sheath called the *epineurium* (Fig. 29.4). To reach the nerve axon, a local anesthetic molecule must traverse any structures surrounding the nerve, such as the paraneurium of the distal sciatic nerve, the epineurium, the perineurium, and the endoneurium, as well as the neuronal plasma membrane. The main barrier to diffusion is the perineurium.[7a] Further, nerves are composed of both neuronal tissues and non-neuronal tissues, such as connective or fatty tissues, and blood vessels. When performing a popliteal sciatic nerve block for example, it should be kept in mind that here, approximately 60% of the nerve cross-section is non-neuronal tissue.[8]

STRUCTURE OF THE AXONAL MEMBRANE

Biologic membranes consist of a molecular lipid bilayer containing proteins adsorbed on the surfaces, as well as embedded in or spanning the hydrocarbon core (Fig. 29.5). The

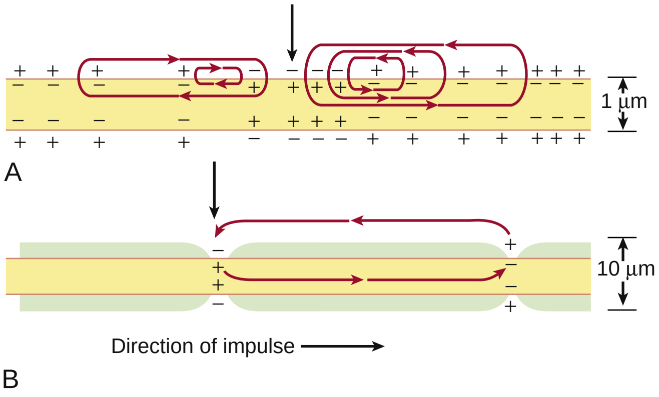

Fig. 29.3 Pattern of local circuit currents flowing during propagation of an impulse in a nonmyelinated C fiber’s axon (A) and a myelinated axon (B). During propagation of impulses, from left to right, current entering the axon at the initial rising phase of the impulse *(large vertical arrows)* passes through the axoplasm (local circuit current) and depolarizes the adjacent membrane. Plus and minus signs adjacent to the axon membrane indicate the polarization state of the axon membrane: negative inside at rest, positive inside during active depolarization under the action potential, and less negative in regions where local circuit currents flow. This ionic current passes relatively uniformly across the nonmyelinated axon, but it is restricted in the myelinated axon to entry at the nodes of Ranvier, several of which are simultaneously depolarized during a single action potential.

character of the bilayer is determined by the phospholipids, which have long hydrophobic fatty acyl tails that lie in the center of the membrane, as well as by the polar hydrophilic head groups, which are usually composed of zwitterionic portions (containing positive and negative charges) that project into the cytoplasm or the extracellular fluid. Within the membrane there is both lateral and rotational diffusion, which allows lipids and certain proteins to migrate in a fluid mosaic, but most membrane proteins are fixed within specific regions of a membrane, anchored by connections to specific proteins of the cell's cytoskeleton.[9] A dynamic interaction exists between the cell's membrane and cytoplasm. Although we focus here on the channel-blocking actions of local anesthetics, it is noteworthy that many other cellular activities, including both metabolic and signal transduction pathways, are modulated by these drugs.

PHYSIOLOGY OF NERVE CONDUCTION

The neural membrane is able to maintain a voltage difference of −60 to −90 mV between the intracellular medium and the cell's outside, because at rest it is relatively impermeable to sodium ions (Na^+) but selectively permeable to potassium ions (K^+). The Na^+/K^+ pump, an

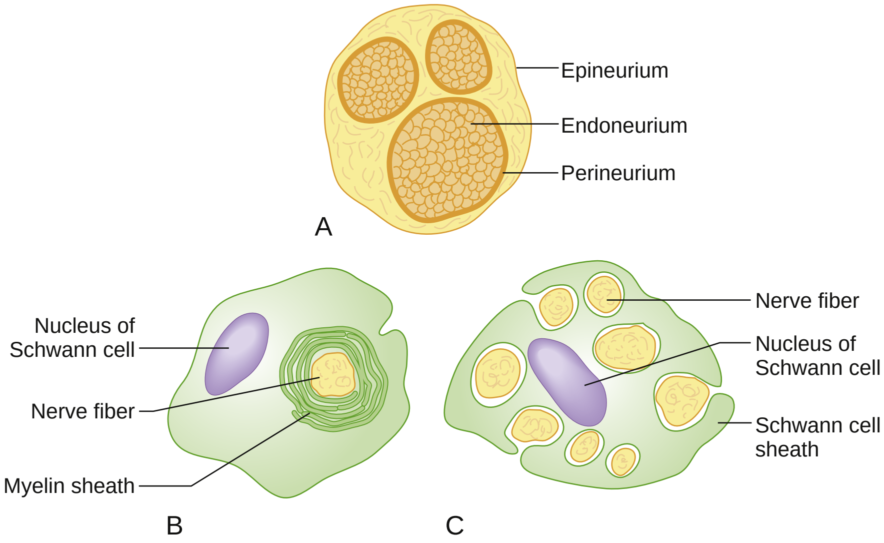

Fig. 29.4 (A) Transverse sections of a peripheral nerve showing the outermost epineurium; the inner perineurium, which collects nerve axons in fascicles; and the endoneurium, which surrounds each myelinated fiber. (B) Each myelinated axon is encased in the multiple membranous wrappings of myelin formed by one Schwann cell, each of which stretches longitudinally more than approximately 100 times the diameter of the axon. The narrow span of axon between these myelinated segments, the node of Ranvier, contains the ion channels that support action potentials. (C) Nonmyelinated fibers are enclosed in bundles of 5 to 10 axons by a chain of Schwann cells that tightly embrace each axon with but one layer of membrane.

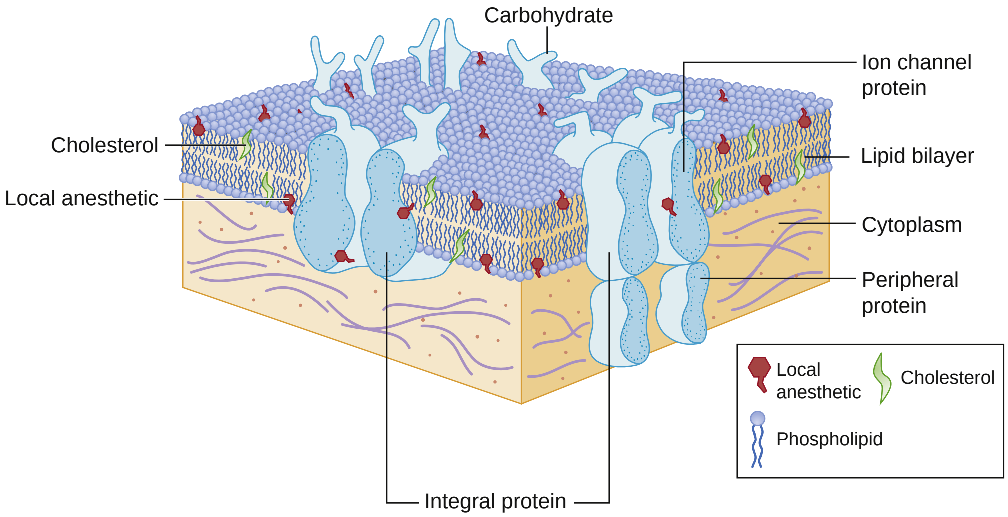

Fig. 29.5 A typical plasma membrane has at its core the lipid bilayer, composed of phospholipids and cholesterol molecules (in an approximately 5:1 ratio) embedding the membrane integral proteins, which are most often glycosylated by extracellular carbohydrates and include receptors and ion channels essential for intercellular communication. “Peripheral proteins” regulate the functions of membrane proteins, chaperone them to the plasma membrane, and stabilize them in the cell through interactions with both the cytoskeleton and the extracellular matrix. Probable membrane locations and protein sites for local anesthetics are also shown.

active, energy-dependent mechanism, sustains the ion gradients that drive this potential difference by constant extrusion of sodium from within the cell in exchange for a net uptake of potassium, with adenosine triphosphate used as an energy source. Although the membrane is relatively permeable to potassium ions, an intracellular-to-extracellular potassium ratio of 150 to 5 mM, or 30:1, is maintained by active removal of potassium as it leaks passively across the plasma membrane into the cell. The nerve at rest behaves largely as a “potassium electrode,” according to the Nernst equation:

$$E_{\mathrm{m}} \approx E_{\mathrm{k}} = \left(\frac{-\mathrm{RT}}{F}\right) \ \ln \ \left(\frac{[\mathrm{K}^+]_{\mathrm{i}}}{[\mathrm{K}^+]_{\mathrm{o}}}\right)$$

where E_m is the membrane potential, E_K is the potassium equilibrium potential, R is the gas constant, T is temperature (kelvin), F is Faraday’s constant, and $[K^+]$ is the potassium ion concentration inside (i) and outside (o) the cell. For potassium, therefore,

$$E_{\mathrm{k}} = -58 \ \log \ 30 \ \text{ or } \ -85.7 \ \text{mV}$$

An opposite situation exists for Na^+, which is at higher concentration outside the cell and has a Nernst potential, E_{Na}, of approximately +60 mV. During an action potential, the nerve membrane transiently switches its higher permeability from K^+ to Na^+, thereby changing the membrane potential from negative to positive, and back again. The progress of this potential change and the underlying events are graphed in Fig. 29.6. They provide a basis for understanding local anesthetic conduction block.

Permeation of ions through membranes occurs via specialized proteins called ion channels.[10] The conformation of these channels is often sensitive to the membrane potential; both Na^+ and K^+ channels in nerve membranes are activated to an “open” conformation by membrane depolarization. Sodium channels, in addition, close to an “inactivated” conformation after their initial activation. A small membrane depolarization extending along an axon from a region of excited membrane, will begin to open both Na^+ and K^+ channels. The Na^+ channels open faster, and the inwardly directed Na^+ current (see Fig. 29.6) depolarizes the membrane further, thereby leading to opening of more Na^+ channels and increasing the inward Na^+ current even further (Fig. 29.7). This sequence of events continues during the *depolarizing phase* until some of the Na^+ channels have become inactivated and enough of the K^+ channels have opened to change the balance of current and result in a net outward current that produces membrane *repolarization* (see Fig. 29.7). After one action potential, the concentrations of Na^+ and K^+ have changed little for the large myelinated fibers but by as much as 10% for the small, nonmyelinated axons. The Na^+ ions entering and K^+ ions leaving the cell as a result of this process are restored by the Na^+/K^+ pump.

Depolarizations too weak to activate enough Na^+ channels to produce a net inward current are below the membrane’s excitability *threshold*. The precise value of the threshold varies in different regions of the cell and can change with time. Directly after an impulse, when some Na^+ channels are still inactivated and some K^+ channels are still activated, the threshold is above its “resting” value and the membrane is “refractory” to stimulation. Over time, as Na^+ inactivation decays and K^+ channels return to their closed conformation, the original resting threshold value is restored. The action potential is a wave of depolarization that is propagated along the axon by continuous coupling between excited and nonexcited regions of membrane. Ionic current (the action current) enters the axon in the excited, depolarized region and then flows down the axoplasm and exits through the surrounding membrane, thereby passively depolarizing this adjacent region (see Fig. 29.3).

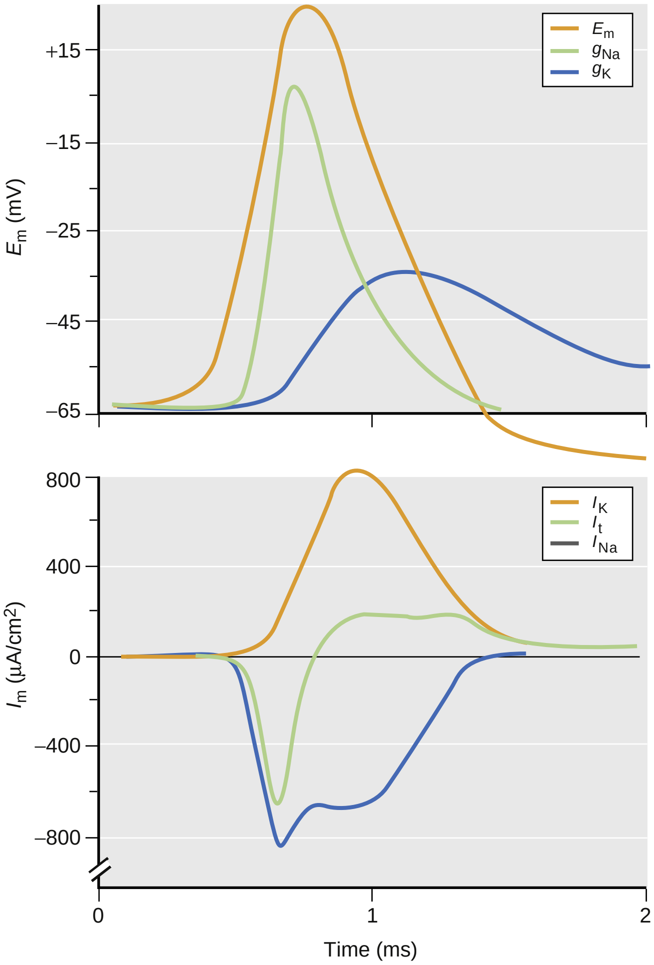

Fig. 29.6 Membrane potential *(E_m)* and the voltage-gated ionic conductance of sodium *(g_{Na})* and potassium *(g_K)*, which determine the corresponding membrane currents I_m (I_{Na} and I_K) during a propagated action potential. Modeled from the original studies of Hodgkin and Huxley on the squid giant axon (see Hodgkin[7b]), these relationships hold for almost all invertebrate and vertebrate nerve fibers. The direction of the total ionic current *(I_t)*, which is the sum of I_{Na} and I_K, is inward (negative values) for the depolarizing phase of the action potential and outward (positive values) for the repolarizing phase. (From Hodgkin A. *The Conduction of the Nervous Impulse*. Springfield, IL: Charles C. Thomas; 1964.)

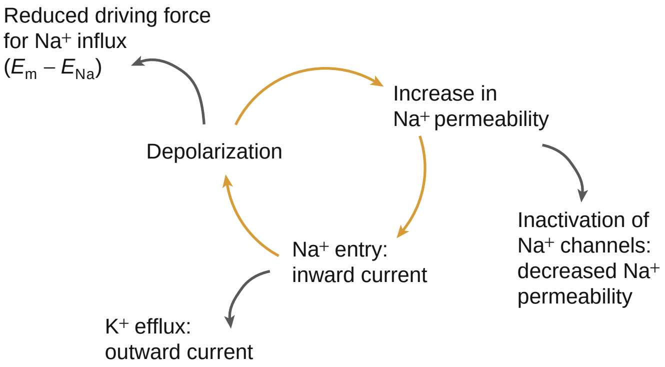

Fig. 29.7 The action potential can be understood in terms of the cyclic relationships between factors contributing to the regenerative, depolarizing phase and the passive, repolarizing phase. Positive factors *(yellow arrows)* increase the rate of depolarization in a positive-feedback loop, with each element in the cycle favoring the subsequent one. Negative factors *(gray arrows)* decrease the depolarization rate by reducing or opposing the related positive factor, with efflux of K^+ eventually dominating the ionic flow and repolarizing the membrane.

Although this *local circuit current* spreads away from the excited zone in both directions, the region behind the impulse, having just been depolarized, is absolutely refractory, and propagation of impulses is thus unidirectional. The local circuit current spreads rapidly along a length of insulated internode in a myelinated axon (see Fig. 29.3), and many nodes of Ranvier in sequence are depolarized to threshold with little intervening delay. Single impulses do not jump from node to node as separate, discrete events; instead, active depolarization occurs simultaneously along several centimeters of the largest axons (see Fig. 29.3). Indeed, the local circuit current is so robust that it can skip past two completely nonexcitable nodes (e.g., blocked by local anesthetic) and successfully stimulate a third node. If excitability is partially reduced, such as by inhibition of some of the Na^+ channels, the amplitude of impulses in successive nodes falls accordingly, a process that can continue for many centimeters.[11] This situation probably occurs during certain phases of local anesthesia, as discussed later. When enough of the Na^+ channels are blocked, local circuit current fails to bring the adjacent resting region to threshold, and the impulse is fully extinguished.

Mechanism of Action of Local Anesthetics (Pharmacodynamics)

ACTIVE FORM

Local anesthetic bases are poorly to sparingly soluble in water but are quite soluble in relatively hydrophobic organic solvents. Therefore as a matter of chemistry (and to optimize shelf life), most of these drugs are formulated as hydrochloride salts. The pK_a of the drug and tissue pH determine the amount of drug that exists in solution as free base or as positively charged cation when injected into living tissue (see earlier). Furthermore, uptake of the drug by tissue, largely via lipophilic adsorption, will also alter its activity, both by shifting the effective pK_a downward, thereby favoring the neutral base form, and by limiting diffusion of the anesthetic away from the site of injection. Moderately hydrophobic local anesthetics block faster than either hydrophilic or highly hydrophobic ones, delivered at the same concentration, for the following reasons. Moderately hydrophilic local anesthetic block, such as lidocaine, are less bound to tissues than very hydrophobic drugs are (e.g., tetracaine) but are still more membrane permeant than very hydrophilic ones (e.g., 2-chloroprocaine). The highly hydrophobic local anesthetics, having higher intrinsic potencies (see Table 29.2), are therefore used in lower concentrations and their diffusion-controlled rate of onset is correspondingly reduced.

Which form of the local anesthetic, charged cation or neutral base, is actually responsible for blockade of impulses? More alkaline solutions of local anesthetics block nerve conduction more effectively. On sheath-free nerves, the rate of inhibition by tertiary amine anesthetics is greater at alkaline than at neutral external pH[12] because membrane permeation, favored by the base over the cationic species, determines the rate of access to the binding site. Direct control of axoplasmic pH (or internal perfusion with permanently charged quaternary amine homologs) shows that the dominant potency derives from the cationic species acting from the cytoplasmic surface.[13,14] The uncharged base also has intrinsic pharmacologic activity, however, which explains the effectiveness of benzocaine as a topical local anesthetic. The local anesthetic attaches to the binding site with its aromatic moiety, while the charged portion protrudes into the sodium channel's lumen.[15]

ELECTROPHYSIOLOGIC EFFECT OF LOCAL ANESTHETICS

The resting membrane potential of nerve is little affected by local anesthetics. As the concentration of local anesthetic applied to the nerve is increased, a decrease in the rate of depolarization and in the peak amplitude of the action potential occurs until the impulse is abolished. By using a "voltage-clamp" procedure, Na^+ currents and their inhibition by local anesthetics can be directly assayed (Fig. 29.8*A*). When the membrane of isolated neurons is rapidly depolarized to a constant value, the time course of ionic currents is observed. Sodium currents during one initial depolarization are reduced by subclinical doses of local anesthetic (e.g., 0.2 mM lidocaine) and totally abolished by clinical doses (e.g., 1% lidocaine ≈40 mM). If the test depolarization is applied repeatedly at frequencies higher than 5 Hz (five pulses per second), the partially depressed (*tonically* inhibited) Na^+ current is further reduced incrementally for each pulse until a new steady-state level of inhibition is reached.[13,16] This frequency-dependent inhibition, also called *phasic inhibition*, is reversed when stimulation is slowed or stopped, and currents return to the level of tonic inhibition observed in the resting nerve. Paralleling the phasic inhibition of Na^+ currents in voltage-clamped membranes is a "use-dependent" blockade of action potentials during normal physiologic function (see Fig. 29.8*B*).

Phasic actions are a manifestation of the selective affinity of local anesthetics for conformations of the Na^+ channel that result from depolarization. Both "open" and "inactivated" states of the channel bind local anesthetics more avidly than the resting state does. Repeated depolarization thus increases the fraction of drug-bound channels; dissociation of these bound drug molecules is usually a slower process than the normal recovery from inactivation (see earlier) and results in the use-dependent accumulation of channels in the blocked condition and the phenomenon of phasic block.

By its selective binding to a channel state, the local anesthetic stabilizes that state. During phasic block, therefore, more inactivated channels become drug bound, and reciprocally, less activation can occur. This relationship between state-dependent affinities and modification of transitions among states through drug binding is known as the "modulated receptor" model.[17] Overall binding of anesthetic is increased by membrane depolarization for two reasons: *more binding sites become accessible* during activation (the "guarded receptor" model) and drug *dissociation* from inactivated channels *is slower* than from resting channels (the modulated receptor model).

The potency of local anesthetics to produce tonic and phasic inhibition is similarly dependent on their structure, hydrophobicity, and pK_a. There appears to be a single, albeit complex, binding site for local anesthetics on the Na^+ channel, with a "tonic" affinity at rest and increased "phasic" affinity occurring as a result of depolarization. The sodium channel can be influenced by a number of drugs or toxins/venoms, and the different sites are numbered. The binding site for local anesthetics is referred to as Site 9, while the outer channel pore, binding site for tetrodotoxin (TTX) or saxitoxin (STX), is referred to as Site 1.

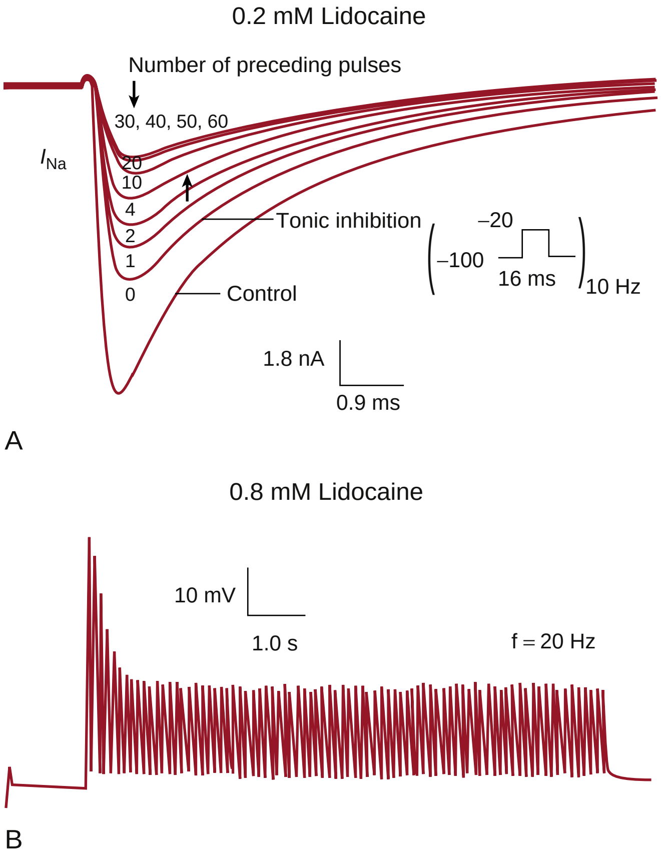

Fig. 29.8 Use-dependent actions of local anesthetics on excitable membrane properties. (A) Ionic Na^+ currents measured by a voltage-clamping technique are transiently activated by brief steps of depolarization applied infrequently (tonic test) or in a train at 10 times per second (phasic test, see E_m pattern in parentheses). After equilibration with 0.2 mM (0.005%) lidocaine, the currents measured tonically are reduced by approximately 30% from the control currents. Application of the phasic train of depolarizations results in a dynamic reduction of currents after each depolarization, with a steady-state value of phasic inhibition reached during the train of 75% of control currents. Recovery of currents to the tonic value occurs within a few seconds when phasic testing stops (not shown). (B) Action potentials are also inhibited in a phasic manner by local anesthetics. After equilibration with 0.8 mM lidocaine (0.02%), the action potential is tonically reduced by approximately 20% from its amplitude in drug-free solution (not shown). Stimulation by a train at 20 stimuli per second induces a phasic inhibition that further reduces the amplitude by about 70% from the control value. As with the ionic currents (A), phasic inhibition of the action potential recovers rapidly when high-frequency stimulation stops.

THE NATURE OF THE LOCAL ANESTHETIC

Binding Site

Intentional mutation of specific amino acids of the Na^+ channel has allowed definition of regions that interact directly with local anesthetics. The major functional protein of the Na^+ channel (the α-subunit) is composed of four homologous "domains" (D-1 to D-4), each of which contains six helical regions (S1 to S6) that span the core of the membrane (Fig. 29.9*A*). Each domain also has a loop, termed the "P region," that links the extracellular ends of its S5 and S6 transmembrane segments; the P regions extend inward between the transmembrane regions such that when the α-subunit folds together, each P loop contributes a quarter of the cylindrical ion "selectivity pore," the narrowest passage of an open channel (see Fig. 29.9*B*). Voltage sensitivity derives from the positive charges located on S4 segments, which slide or swing "outward" in response to membrane depolarization. By linkages still unknown, this movement of S4 results in a conformational rearrangement of the S6 segments, which form the inner, cytoplasmic entry to the channel. Closed-to-open channel gating results from movement of the S6 segments, whereas inactivation gating results from binding of the cytoplasmic loop located between D-3 and D-4 to the cytoplasmic opening of the channel.

Local anesthetics bind in the "inner vestibule" of the closed Na^+ channel (see Fig. 29.9*C*). Amino acid mutations in the S6 segments of D-1, D-3, and D-4 all modify local anesthetic action, thus suggesting either that these regions form a "pharmacophore" small enough to simultaneously contact the drug at three surfaces or that the local anesthetic molecule moves rapidly among these three segments. The rate constant for binding of local anesthetic to

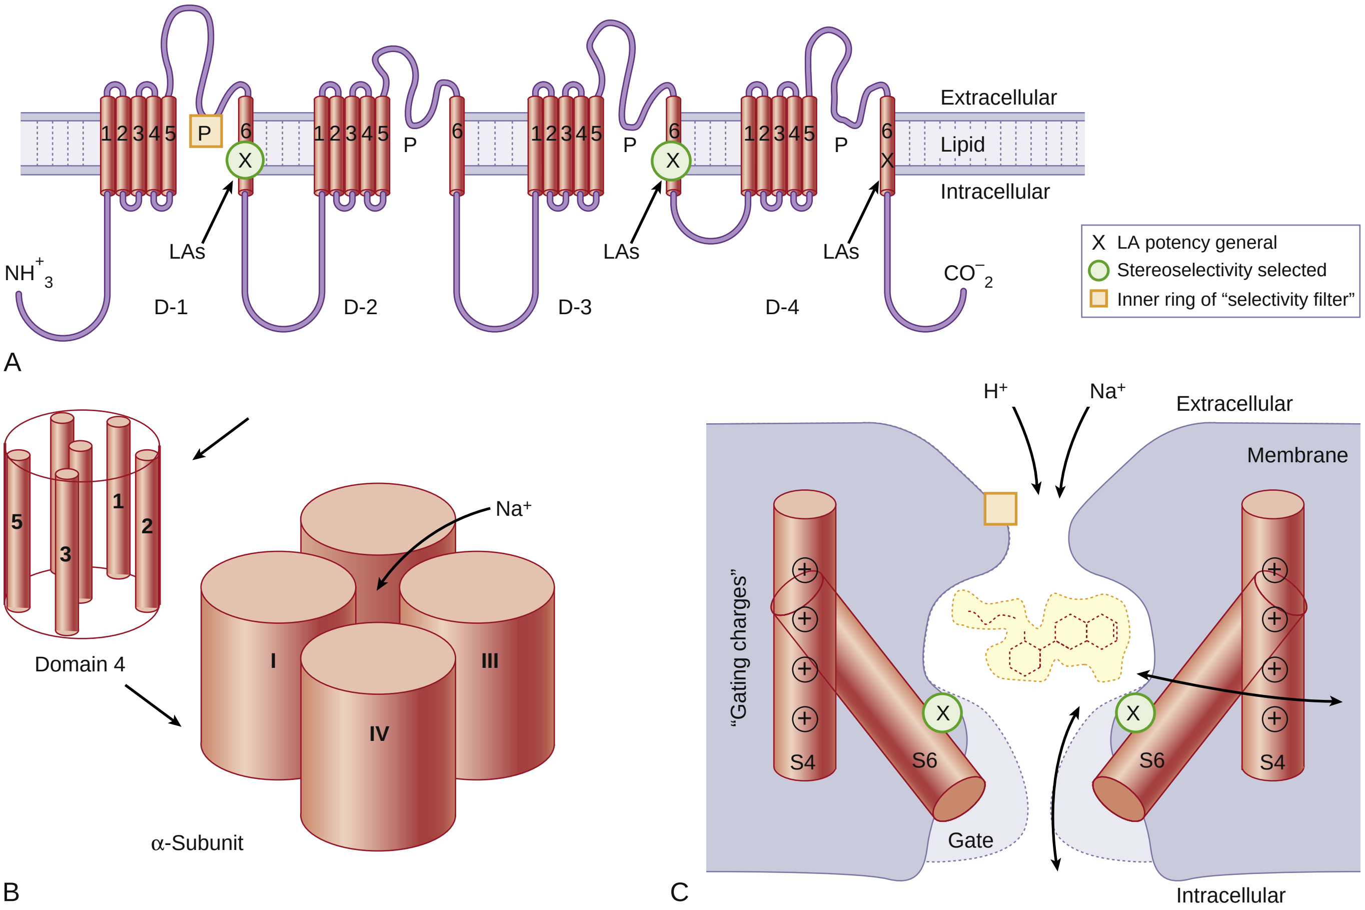

Fig. 29.9 Structural features of the Na^+ channel that determine local anesthetic *(LA)* interactions. (A) Consensus arrangement of the single peptide of the Na^+ channel α-subunit in a plasma membrane. Four domains with homologous sequences (D-1 through D-4) each contain six α-helical segments that span the membrane (S1 to S6). Each domain folds within itself to form one cylindrical bundle of segments, and these bundles converge to form the functional channel's quaternary structure (B). Activation gating leading to channel opening results from primary movement of the positively charged S4 segments in response to membrane depolarization (see panel C). Fast inactivation of the channel follows binding to the cytoplasmic end of the channel of part of the small loop that connects D-3 to D-4. Ions travel through an open channel along a pore defined at its narrowest dimension by the P region formed by partial membrane penetration of the four extracellular loops of protein connecting S5 and S6 in each domain. Intentional, directed mutations of different amino acids on the channel indicate residues that are involved in LA binding in the inner vestibule of the channel (X on S6 segments), at the interior regions of the ion-discriminating "selectivity filter" (*square* on the P region), and which are also known to influence stereoselectivity for phasic inhibition (*circle*, also on S6 segments). (C) Schematic cross section of the channel speculating on the manner in which S6 segments, forming a "gate," may realign during activation to open the channel and allow entry and departure of a bupivacaine molecule by the "hydrophilic" pathway. The closed (inactivated) channel has a more intimate association with the LA molecule, whose favored pathway for dissociation is no longer between S6 segments (the former pore) but now, much more slowly, laterally between segments and then through the membrane, the "hydrophobic" pathway. Na^+ ions entering the pore will compete with the LA for a site in the channel, and H^+ ions, which pass very slowly through the pore, can enter and leave from the extracellular opening, thereby protonating and deprotonating a bound LA molecule and thus regulating its rate of dissociation from the channel.

the closed Na^+ channel is larger for the more hydrophobic molecules, which suggest that drug molecules can reach the binding site (and depart from it) through a "hydrophobic" pathway. The charged species of local anesthetics dissociates much more slowly from closed and inactivated Na^+ channels than the neutral form does, which suggests that an ionic bond may be involved in drug binding or that the charged molecule moves only slowly along the hydrophobic pathway. In brief, hydrophobicity delivers the drug to the receptor and charge keeps it there.

NEUROPHYSIOLOGIC ASPECTS OF PHASIC INHIBITION

Different fiber types in the nerve are affected differently during local anesthesia. At least part of this difference arises from pharmacokinetic factors. At the onset of and during recovery from clinical block, in particular, longitudinal and radial diffusion of drug will produce concentration variations within and along the nerve. This variation is superimposed on the dynamic use-dependent inhibition to provide variable propagation, which depends on a fiber's geometry, position within the nerve, and functional as well as electrophysiologic properties.

Different fiber types are also differentially sensitive to local anesthetic blockade. In vivo experiments in which continuous superperfusion of peripheral nerve allows equilibration with drug, and experiments in which a drug bolus is delivered by percutaneous injection,[18] analogous to clinical peripheral nerve block, show that small myelinated axons (Aγ motor and Aδ sensory fibers) are the most susceptible to impulse suppression. Next in order of block are the large myelinated (Aα and Aβ) fibers, and the least susceptible are the small, nonmyelinated C fibers. In fact, in this last group, impulses in the slowest conducting population (conduction velocity of 0.5-0.8 m/s) are the most resistant to local anesthetic.[18] Clinically, testing of block efficacy is often performed using methods that target Aδ sensory fibers, so these findings suggest that loss of temperature or pin-prick discrimination does not guarantee complete and reliable block of all sensory modalities.

Selective Block of Na^+ Channel Isoforms

Nine different mammalian Na^+ channels have been physiologically identified and their genes have been sequenced. At least four of them are found in peripheral neurons, and some are exclusively associated with nociceptive afferents. Obviously, it would be clinically advantageous to selectively inhibit these channels and thus prevent or reduce pain while sparing other functions. Although selective channel blockade has been attained with naturally occurring small peptide toxins,[19] relatively little selective blockade by local anesthetics has been reported,[20] probably because the local anesthetic pharmacophore is too similar among the different channel isoforms and the local anesthetic molecules themselves have several rotational axes, which makes them poor structural templates for selecting among static binding pockets. Selectively blocking different sodium channel isoforms can lead to distinct effects because they are not evenly distributed across the nerve and react differently to activation. Specifically, one of the main functions of the Nav1.7 isoform is to act as an amplifier in the terminals of primary sensory neurons, while Nav1.8 is vital to the repetitive firing in these neurons, and Nav1.9 is able to generate persistent currents which can increase membrane excitability.[21] Some recent advances which hold promise to improve nerve block properties of local anesthetics are summarized toward the end of this chapter.

Sodium Channel Isoforms and Their Contribution to Human Diseases Characterized by Pain or Pain Insensitivity

We now know several mutations in the prototypical neuronal sodium channels (Nav1.7, 1.8, and 1.9) which can lead to states of either spontaneous pain[22,23] or profound and selective impairment of pain sensitivity.[24] This depends on the type of mutation and mode of inheritance. For example, mutations in Nav1.7 may lead to loss of channel function and, in the most extreme form, congenital insensitivity to pain. In contrast, activating mutations in the same channel can trigger erythromelalgia or paroxysmal extreme pain disorder.[21] Molecular studies reveal that these disorders involve several distinct types of mutations in NaV1.7 sodium channels.[22,23] When these channels are inserted into cells that lack sodium channels, they generate spontaneous, temperature-sensitive inward currents.[21] Another recent finding was that certain preclinical models of visceral pain (e.g., cystitis) are not responsive to therapies specifically targeting the NaV1.7 channels, while block of NaV1.9 channels was effective.[25] Lastly, it is important to note that mutations in nonneuronal sodium channels can have profound clinical consequences as well. For example, mutations of the Nav1.4 sodium channel isoform in skeletal muscle can produce myotonia, periodic paralysis, and congenital myasthenia.[26]

Aberrant impulses, which are often considered the hallmarks of various diseases of excitable membranes, such as abnormal repetitive firing in neuropathic pain or in certain types of inherited skeletal myotonia, are abolished by systemic lidocaine in doses that do not block normal propagating impulses. Conditions for the sensitivity of such impulses to local anesthetics, such as lidocaine, appear to result from the patterns of impulse spikes superimposed on slow membrane depolarizations caused by abnormal expression of Na^+ channels rather than from selective sensitivity of certain subtypes of channels to these drugs.[27]

SUMMARY OF LOCAL ANESTHETIC MECHANISMS

Impulse blockade by local anesthetics may be summarized by the following chronology:

1. Solutions of local anesthetic are deposited near the nerve. Removal of free drug molecules away from this locus is a function of tissue binding, removal by the circulation, and local hydrolysis of aminoester anesthetics. The net result is penetration of the nerve sheath by the remaining free drug molecules.
2. Local anesthetic molecules then permeate the nerve's axon membranes and reside there and in the axoplasm. The speed and extent of these processes depend on a particular drug's pK_a and on the lipophilicity of its base and cation species.

3. Binding of local anesthetic to sites on voltage-gated Na^+ channels prevents opening of the channels by inhibiting the conformational changes that underlie channel activation.
4. During onset of and recovery from local anesthesia, impulse blockade is incomplete and partially blocked fibers are further inhibited by repetitive stimulation, which produces an additional, use-dependent binding to Na^+ channels.
5. One local anesthetic binding site on the Na^+ channel may be sufficient to account for the drug's resting (tonic) and use-dependent (phasic) actions.
6. The clinically observed rates of onset and recovery from blockade are governed by the relatively slow diffusion of local anesthetic molecules into and out of the whole nerve, not by their much faster binding and dissociation from ion channels. A clinically effective block that may last for hours can be accomplished with local anesthetic drugs that dissociate from Na^+ channels in a few seconds.

Clinical Pharmacology

Successful use of regional anesthesia requires knowledge of the pharmacologic properties of the various local anesthetic drugs, as well as technical skill in performance of the nerve block. Local anesthetic requirements vary considerably, depending on factors such as the type of block, surgical procedure, and physiologic status of the patient.

Commonly used aminoester local anesthetics include procaine, chloroprocaine, tetracaine, and the first true local anesthetic, cocaine. Commonly used aminoamides include lidocaine, mepivacaine, prilocaine, bupivacaine (the racemic form and its levoenantiomer), ropivacaine, and etidocaine. The ester and amide local anesthetics differ in their chemical stability, locus of biotransformation, and allergic potential. Amides are extremely stable, whereas esters are relatively unstable in solution. Aminoesters are hydrolyzed in plasma by cholinesterase enzymes, but the amides undergo enzymatic degradation in the liver. Two exceptions to this trend include cocaine, an ester that is metabolized predominantly by hepatic carboxylesterase, and articaine, an amide local anesthetic widely used in dentistry that is inactivated by plasma carboxylesterase-induced cleavage of a methyl ester on the aromatic ring.

p-Aminobenzoic acid is one of the metabolites of ester-type compounds that can induce allergic-type reactions in a small percentage of patients. The aminoamides are not metabolized to *p*-aminobenzoic acid, and reports of allergic reactions to these agents are extremely rare.

GENERAL CONSIDERATIONS

Clinically important properties of the various local anesthetics include potency, speed of onset, duration of anesthetic action, and differential sensory/motor blockade. As previously indicated, the profile of individual drugs is determined by their physicochemical characteristics (see Table 29.2).

Anesthetic Potency

Hydrophobicity appears to be a primary determinant of intrinsic anesthetic potency[5] because the anesthetic molecule must penetrate into the nerve membrane and bind at a partially hydrophobic site on the Na^+ channel. Clinically, however, the correlation between hydrophobicity and anesthetic potency is not as precise as in an isolated nerve. Differences between in vitro and in vivo potency may be related to a number of factors, including local anesthetic charge and hydrophobicity (which influence partitioning into and transverse diffusion across biologic membranes) and vasodilator or vasoconstrictor properties (which influence the initial rate of vascular uptake from injection sites into the central circulation).

Onset of Action

The onset of conduction block in isolated nerves is related to the physicochemical properties of the individual agents. In vivo latency is also dependent on the dose or concentration of local anesthetic used. For example, 0.75% bupivacaine has more rapid onset than 0.25%. Chloroprocaine demonstrates a rapid onset of action in humans because its low systemic toxicity permits its use in high concentrations (3%).

Duration of Action

The duration of action of the various local anesthetics differs markedly. Procaine and chloroprocaine have a short duration of action. Lidocaine, mepivacaine, and prilocaine produce a moderate duration of anesthesia, whereas tetracaine, bupivacaine, ropivacaine, and etidocaine have the longest durations.

In humans, the duration of anesthesia is markedly influenced by the peripheral vascular effects of the local anesthetic drugs. Many local anesthetics have a biphasic effect on vascular smooth muscle; at low concentrations these agents tend to cause vasoconstriction, whereas at higher, clinically administered concentrations, they cause vasodilation.[28] However, differences exist in the degree of vasodilator activity of the various drugs. The effects of local anesthetics on vascular tone and regional blood flow are complex and vary according to concentration, time, and the particular vascular bed near the site of application. As a practical example, the topical local anesthetic formulation EMLA (eutectic mixture of the local anesthetics lidocaine and prilocaine) vasoconstricts cutaneous vessels initially and through most of the first hour of application, but vasodilation is observed after 2 or more hours of application.

Differential Sensory and Motor Blockade

Another important clinical consideration is the ability of local anesthetic agents to cause differential inhibition of sensory and motor activity. Bupivacaine became popular in the 1980s for epidural blocks because it was better than the previously available long-acting agents (e.g., etidocaine) in producing adequate antinociception without profound inhibition of motor activity, particularly when dilute solutions are used. Bupivacaine is widely used epidurally for obstetric analgesia and postoperative pain management because it can provide acceptable analgesia with only mild muscle weakness. Additional observations on the sensory selectivity of newer local anesthetics are detailed later in the section on chiral local anesthetics.

Traditional texts often state that small-diameter axons, such as C fibers, are more susceptible to local anesthetic block than larger-diameter fibers. However, when careful measurements are made of single-impulse annihilation in individual nerve fibers, exactly the opposite differential susceptibility is noted (see earlier).[29,30] Repetitive stimulation, such as occurs during propagation of trains of impulses, produces further, phasic inhibition of excitability, but it is not clear how this will affect a functionally selective failure of impulses. The length of drug-exposed nerve in the intrathecal space, imposed by anatomic restrictions, can perhaps explain clinically documented differential spinal or epidural blockade, with longer drug-exposed regions yielding block by lower concentrations of local anesthetic.[31] However, this reasoning does not explain the functionally differential loss from peripheral nerve block. Other factors may include actual spread of the drug along the nerve or its selective ability to inhibit Na^+ channels over K^+ channels,[32] which in itself can produce a differential block because these channels are present in very different proportions in different types of nerves. As a result of these confounding factors, conclusions about fiber-type involvement in chronic pain syndromes based on the dose or concentration requirement for pain relief in diagnostic nerve blockade should not be made.[33]

FACTORS INFLUENCING ANESTHETIC ACTIVITY IN HUMANS

Dosage of Local Anesthetic

As the dosage of local anesthetic is increased, the probability and duration of satisfactory anesthesia increases and the time to onset of block is shortened. The dosage of local anesthetic can be increased by administering either a larger volume or a more concentrated solution. For example, increasing the concentration of epidurally administered bupivacaine from 0.125% to 0.5% while maintaining the same volume of injectate (10 mL) resulted in shorter latency, an improved incidence of satisfactory analgesia, and a longer duration of sensory analgesia.[34] The volume per se of anesthetic solution probably influences the spread of anesthesia. For example, 30 mL of 1% lidocaine administered into the epidural space produced a level of anesthesia that was 4.3 dermatomes higher than that achieved when 10 mL of 3% lidocaine was given.

In selecting the volume and concentration for a specific block in a particular patient, clinicians must balance the risk of adverse effects from excessive dosing (e.g., systemic toxicity, excessive motor or autonomic blockade) against the increased risk of block failure if an inadequate volume or concentration is chosen. The degree to which additional volume can compensate for imprecise needle placement varies among different blocks. With the advent of very precise needle placement using ultrasound-guided blockade, it has become clear that the median effective volume for obtaining successful blockade can be achieved with smaller volumes than have been recommended from some previous clinical series based on traditional methods of needle localization. For example, in a recent dose-finding randomized trial for femoral nerve blockade, the median volumes for 50% or 95% success in obtaining dense sensory and motor block at 30 minutes under ultrasound guidance were 57% and 54% of the corresponding volumes with the use of nerve stimulation.[35] Interested readers will note the very wide confidence intervals found in this study and are encouraged to read recent work on some statistical design issues for dose-response studies involving all types of anesthetics.[36] As limited by toxicity considerations, the aim in most clinical situations should be to choose doses that provide high success rates; that is, an effective dose (ED) in 95% of patients (ED_{95}) is generally a more relevant guide to dose selection than an ED_{50} dose. These considerations are especially salient when performing regional anesthesia for patients with chronic pain, hyperalgesia, or a history of previous failed regional anesthesia. Also, decreasing the dose substantially may provide a satisfactory block after 30 minutes (a common endpoint for clinical studies), but at the same time, the block may have a decreased duration of action. Duration of action is important such that the block will cover the intensely painful period after surgery, and if this period is longer than could be achieved using plain local anesthetics, and in cases where continuous techniques are not feasible, adjuvants/additives may help in prolonging the block.

Addition of Additives

Epinephrine. Vasoconstrictors, usually epinephrine, are frequently included in local anesthetic solutions to decrease the rate of vascular absorption, thereby allowing more anesthetic molecules to reach the nerve membrane and thus improve the depth and duration of anesthesia. The use of epinephrine as a marker for inadvertent intravascular injection continues to be sensible, even though false negatives and false positives can occur, such as difficulty in interpretation for specific patient groups as with parturients and patients under anesthesia or on β-blockers.[37] Clinically used solutions typically contain 5 μg/mL or 1:200,000 of epinephrine, reflecting a balance between efficacy and vasoconstriction versus systemic side effects of epinephrine. The extent to which epinephrine prolongs the duration of anesthesia depends on the specific local anesthetic used and the site of injection. Epinephrine will significantly extend the duration of both infiltration anesthesia and peripheral nerve blockade with shorter-duration agents (e.g., lidocaine); epinephrine produces mild intensification of blockade but only most modest prolongation of epidural or peripheral blocks with bupivacaine.[36] Activation of α_2-adrenergic receptors in the spinal cord may contribute to the beneficial effect of epidural epinephrine.

Clonidine and Dexmedetomidine. The α-2 agonist clonidine prolongs the action of local anesthetics by about 2 hours with wide variation between studies[38], and its conjectured mechanisms of action include actions on α-2 receptors and on hyperpolarization-induced currents.[39] However, there is a large number of negative studies, and adverse systemic events are of concern, including hypotension, bradycardia, and sedation, such that limiting the clonidine dose to 0.5 to 1 μg/kg of ideal body weight has been proposed. Dexmedetomidine is a much more specific α-2 agonist, and prolongs both motor and sensory block by long-acting local anesthetics by approximately 4 hours.[40] Similar to clonidine, dexmedetomidine has also been shown to block the hyperpolarization-induced current.[41]

Nevertheless, risk of systemic adverse effects remains high, and optimal doses have not been determined. There seems to be no increased risk of neurotoxicity when clonidine or dexmedetomidine are used as nerve block adjuvants.

Buprenorphine. The partial μ-opiate receptor agonist, buprenorphine, intensifies blockade by two mechanisms, namely blockade of κ- and δ-opioid receptors, and blockade of voltage-gated sodium channel-blocking properties.[42] Blockade by long-acting local anesthetics is prolonged by about 6 hours, but at the price of a high incidence of nausea and vomiting, such that the use of buprenorphine has largely been abandoned.[43] Buprenorphine is considered safe in terms of neurotoxicity.

Dexamethasone. The most effective adjuvant for prolonging block duration with minimal side effects currently available is dexamethasone, able to prolong duration of medium-acting local anesthetics by 2 to 3 hours, and the block of long-acting local anesthetics by up to 10 hours on average.[44] Blocks can be prolonged by intravenous or perineural administration of dexamethasone. Despite the fact that perineural administration of dexamethasone seems to be more effective than systemic use, many providers use systemic dexamethasone to avoid mixing drugs which were not designed to be administered together, circumvent the problem of off-label perineural use, and profit from the antiemetic effects of systemic dexamethasone. Doses between 4 and 10 mg have typically been used in adults.[45] The precise mechanism of action of dexamethasone is not understood and the potential for neurotoxic side effects has not been adequately studied.

Site of Injection

The most rapid onset but the shortest duration of action occurs after intrathecal or subcutaneous administration of local anesthetics. The longest latencies and durations are observed after conventional non–ultrasound-guided large-volume brachial plexus blocks. For example, intrathecal bupivacaine will usually produce anesthesia within 5 minutes that will persist for 3 to 4 hours. However, when bupivacaine is administered for brachial plexus blockade, the onset time is approximately 20 to 30 minutes, and the duration of anesthesia (or at least analgesia) averages 10 hours.[46] These differences in the onset and duration of anesthesia and analgesia are due in part to the particular anatomy of the area of injection, which will influence the rate of diffusion and vascular absorption and, in turn, affect the amount of drug used for various types of regional anesthesia. In the subarachnoid space, for example, the lack of a nerve sheath around the spinal cord and deposition of the local anesthetic solution in the immediate vicinity of the spinal cord are responsible for the rapid onset of action, whereas the relatively small amount of drug used for spinal anesthesia probably accounts for the short duration of conduction block.

In contrast, the onset of brachial plexus blockade is slow because the anesthetic agent is usually deposited at some distance from the nerve and must diffuse through various tissue barriers before reaching the nerve membrane. The prolonged block with brachial plexus blockade may be related to several factors, including comparatively slow rates of vascular absorption from the brachial plexus sheath, larger doses of drug required for this regional anesthetic technique, and comparatively long segments of nerves exposed to local anesthetic.

Carbonation and pH Adjustment of Local Anesthetics

The addition of sodium bicarbonate to a solution of local anesthetic applied to an isolated nerve accelerates the onset and decreases the minimum concentration (C_m) required for conduction blockade by increasing pH and increasing the share of uncharged local anesthetic molecules that can more easily diffuse into the nerve cell.[47] Although the effect of carbon dioxide on local anesthetic activity is easily demonstrable in isolated nerve, controversy exists concerning the clinical utility of carbonated local anesthetic solutions[48] and the widespread introduction of ultrasound-guided nerve blockade with faster and more reliable block onset has decreased the relevance of carbonation, at least for peripheral nerve blockade.

Mixtures of Local Anesthetics

Mixtures of local anesthetics for regional anesthesia are sometimes used in an effort to compensate for the short duration of action of certain rapidly acting agents such as chloroprocaine and lidocaine, and the long latency of longer-acting agents such as tetracaine and bupivacaine. Mixtures of chloroprocaine and bupivacaine theoretically offer significant clinical advantages because of the rapid onset and low systemic toxicity of chloroprocaine and the long duration of action of bupivacaine; however, clinical results in studies of combinations have been mixed.[49] The use of catheter techniques for many forms of regional anesthesia makes it possible to begin with a rapid-onset local anesthetic such as lidocaine, mepivacaine, or chloroprocaine and then follow with an infusion of either a shorter-acting or longer-acting local anesthetic thereafter. Clinicians should be cautioned to not use maximum doses of two local anesthetics in combination in the mistaken belief that their toxicities are independent.[50] Toxicity in fact, is additive. Moreover, the use of ultrasound-guided nerve blockade has, in general, led to a decreased onset time and has made mixing local anesthetics less clinically relevant.

Pregnancy

The spread and depth of epidural and spinal anesthesia are greater in pregnant than in nonpregnant women. The effects of pregnancy on local anesthetic potency may reflect a combined effect of mechanical factors associated with pregnancy (i.e., dilated epidural veins decrease the volume of the epidural and subarachnoid spaces) and direct effects of hormones, especially progesterone, on the susceptibility of nerves to conduction blockade by local anesthetics.[51] Hormonal alterations are probably the more important of these two factors because greater spread of epidural anesthesia is already observed during the first trimester of pregnancy,[52] before any gross change in vascular dimensions within the epidural or subarachnoid spaces. The dosage of local anesthetics should probably be reduced in patients in all stages of pregnancy.

Choice of Local Anesthetic for Various Regional Anesthetic Procedures

On the basis of anatomic considerations, regional anesthesia may be divided into infiltration anesthesia, intravenous regional anesthesia (IVRA), peripheral nerve blockade (including plexus blockade), central neural blockade, and topical anesthesia. An additional method of local anesthetic injection, tumescent anesthesia, is included because it is widely used in office-based plastic surgery.

INFILTRATION ANESTHESIA

Any local anesthetic may be used for infiltration anesthesia. Onset of action is almost immediate for all agents after intradermal or subcutaneous administration; however, the duration of anesthesia varies (Table 29.4). Epinephrine will prolong the duration of infiltration anesthesia by all local anesthetic drugs, although this effect is most pronounced when epinephrine is added to lidocaine. The choice of a specific drug for infiltration anesthesia largely depends on the desired duration of action.

The dosage of local anesthetic required for adequate infiltration anesthesia depends on the extent of the area to be anesthetized and the expected duration of the surgical procedure. When large surface areas have to be anesthetized, large volumes of dilute anesthetic solutions should be used. These considerations are particularly important when performing infiltration anesthesia in infants and smaller children. As an example, consider a 4-kg infant receiving infiltration anesthesia with the maximum safe dose of lidocaine, 5 mg/kg. Dosing to 5 mg/kg permits 20 mg/4 kg, which is 1 mL of a 2% solution or 4 mL of a 0.5% solution. Lidocaine is effective for infiltration in concentrations as dilute as 0.3% to 0.5%, so the more dilute solution can be used more safely to anesthetize a larger area.

Patients frequently experience pain immediately after subcutaneous injection of local anesthetic solutions, in part because of the acidic nature of these solutions, and in part because lidocaine briefly activates transient receptor potential vanilloid-1 (TRPV-1) and transient receptor potential ankyrin-1 (TRPA-1) channels, causing pain, before sodium channel block subsequently silences the neuron.[53] Alkalinization of lidocaine solutions by the addition of sodium bicarbonate immediately before injection reduces pain on skin infiltration[54] and may improve onset (see earlier).

Infiltration analgesia and indwelling wound catheters are used increasingly as components of multimodal postoperative analgesia.[55-57] In particular, sustained-release formulations such as Exparel have been introduced into clinical practice (see the section Development of Prolonged-Duration and Sensory- or Nociceptive-Selective Local Anesthetics).

INTRAVENOUS REGIONAL ANESTHESIA

IVRA (Bier's block) involves the intravenous administration of a local anesthetic into a tourniquet-occluded limb. The local anesthetic diffuses from the peripheral vascular bed to nonvascular tissue such as axons and nerve endings. Both the safety and the efficacy of this regional anesthetic procedure depend on interruption of blood flow to the involved limb and gradual release of the occluding tourniquet.

Lidocaine and prilocaine have been the drugs used most frequently for IVRA. Drugs with a high cardiotoxic potential such as bupivacaine should not be used for IVRA. One might suppose a safety advantage with the aminoester-linked compounds because of their hydrolysis in blood; however, thrombophlebitis has been reported with chloroprocaine. In general, approximately 3 mg/kg (40 mL of a 0.5% solution) of preservative-free lidocaine without epinephrine is used for upper extremity procedures. For surgical procedures on the lower limbs, 50 to 100 mL of a 0.25% lidocaine solution have been used. Even though the safety profile of IVRA is considered very good, seizures have been reported with lidocaine doses as low as 1.4 mg/kg of lidocaine, and cardiovascular collapse (CC) can occur.[58]

TABLE 29.4 Infiltration Anesthesia

	PLAIN SOLUTION			EPINEPHRINE-CONTAINING SOLUTION	
Drug	**Concentration (%)**	**Maximum Dose (mg)**	**Duration (min)**	**Maximum Dose (mg)**	**Duration (min)**
SHORT DURATION					
Procaine	1-2	500	20-30	600	30-45
Chloroprocaine	1-2	800	15-30	1000	30
MODERATE DURATION					
Lidocaine	0.5-1	300	30-60	500	120
Mepivacaine	0.5-1	300	45-90	500	120
Prilocaine	0.5-1	350	30-90	550	120
LONG DURATION					
Bupivacaine	0.25-0.5	175	120-240	200	180-240
Ropivacaine	0.2-0.5	200	120-240	250	180-240

PERIPHERAL AND TRUNCAL NERVE BLOCKADE

Regional anesthetic procedures that inhibit conduction in fibers of the peripheral nervous system can be classified together under the general category of peripheral nerve blockade. This form of regional anesthesia has been arbitrarily subdivided into minor and major nerve blocks. Minor nerve blocks are defined as procedures involving single nerve entities such as the ulnar or radial nerve, whereas major nerve blocks involve the blockade of two or more distinct nerves or a nerve plexus or the blockade of very large nerves at more proximal sites (i.e., the femoral and sciatic nerves).

Most local anesthetic drugs can be used for minor nerve blocks. The onset of blockade is rapid with most drugs, and the choice of drug is determined primarily by the required duration of anesthesia. A classification of the various drugs according to their duration of action is shown in Table 29.5. It has become possible to define the minimum local anesthetic volume for ultrasound-guided peripheral nerve blockade and across several nerves; the volume was approximately 0.1 mL per mm^2 of nerve cross-sectional area.[59,60] However, as mentioned earlier, minimal volume to achieve sensory blockade 30 minutes after block may also mean decreased duration of the block as compared to "traditional" high volumes clinicians were accustomed to using during stimulator-guided regional anesthesia.

Brachial plexus blockade for upper limb surgery is the most common major peripheral nerve block technique, but many lower extremity procedures are now carried out under peripheral nerve blocks for anesthesia or postoperative analgesia. A significant difference exists between the onset times of various agents when these blocks are used (Table 29.6). In general, agents of intermediate potency exhibit a more rapid onset than the more potent compounds do.

Next to surgeries on the upper and lower extremities, peripheral nerve blocks have become popular for treating pain after thoracic and abdominal procedures. In the case of superficial thoracic surgery such as breast surgery, field blocks such as the PECS-1 and PECS-2 and Serratus plane block have been successfully used. Proximal intercostal nerve blocks and paravertebral blocks are also employed for mastectomies and reconstructions by some institutions, but more research is needed to define efficacy, precise indications, and procedure-specific details of technique.[61] Paravertebral and proximal intercostal techniques appear equally effective as epidural analgesia in treating pain after video-assisted thoracoscopic surgery (VATS) and thoracotomy and have fewer side effects.[62]

PERINEURAL AND PLEXUS INFUSIONS

Local anesthetics are being administered by continuous infusion for several days after surgery[56,63] or for periods of weeks to months for the treatment of chronic malignant and

TABLE 29.5 Minor Nerve Blocks

				AVERAGE DURATION (MIN)	
Drug	**Usual Concentration (%)**	**Usual Volume (mL)**	**Dose* (mg)**	**Plain Solutions**	**Epinephrine-Containing Solutions**
Procaine	2	5-20	100-400	15-30	30-60
Chloroprocaine	2	5-20	100-400	15-30	30-60
Lidocaine	1	5-20	50-200	60-120	120-180
Mepivacaine	1	5-20	50-200	60-120	120-180
Prilocaine	1	5-20	50-200	60-120	120-180
Bupivacaine	0.25-0.5	5-20	12.5-100	180-360	240-420
Ropivacaine	0.2-0.5	5-20	10-100	180-360	240-420

*Doses are for a 70-kg adult. For pediatric doses, see Chapter 76.

TABLE 29.6 Major Nerve Blocks

Drug	**Usual Concentration (%)**	**Usual Volume (mL)**	**Maximum Dose (mg) Without/With Epinephrine**	**Onset (min)**	**Duration (min)**
Lidocaine	1-2	30-50	350/500	10-20	120-240
Mepivacaine	1-1.5	30-50	350/500	10-20	180-300
Prilocaine	1-2	30-50	400/600	10-20	180-300
Bupivacaine	0.25-0.5	30-50	175/225	20-30	360-720
Levobupivacaine	0.25-0.5	30-50	200/225	20-30	360-720
Ropivacaine	0.2-0.5	30-50	200/250	20-30	360-720

See also Chapter 46. Doses are for a 70-kg adult receiving epinephrine-containing solutions. Doses should be reduced for children, for patients with specific risk factors, and for blocks in specific locations (e.g., interscalene). When two or more blocks are performed together, the sum of the doses for each of the individual blocks should not exceed the max dose listed here.

nonmalignant pain. However, because of the poor sensory selectivity of contemporary local anesthetics, prolonged use of catheters at times conflicts with the paradigm of fast mobilization, especially as neuraxial and lower extremity techniques are concerned. With prolonged infusions there is a theoretical potential for delayed systemic accumulation and toxicity. However, the activation of the acute-phase response after trauma or surgery also leads to an increase in α-1 acidic glycoprotein, which is potent at binding free local anesthetics and decreases the risk of cumulation of free local anesthetic.[64]

CENTRAL NEURAL BLOCKADE

Any of the local anesthetic drugs may be used for epidural anesthesia (Table 29.7), although procaine and tetracaine are rarely used because of their long onset times. Drugs of intermediate potency produce surgical anesthesia of 1 to 2 hours' duration, whereas long-acting drugs usually produce 3 to 4 hours of anesthesia. The duration of short- and intermediate-acting drugs is significantly prolonged by the addition of epinephrine (1:200,000), but the duration of long-acting drugs is only minimally affected by epinephrine. The onset of lumbar epidural anesthesia occurs within 5 to 15 minutes after the administration of chloroprocaine, lidocaine, mepivacaine, and prilocaine. Bupivacaine has a slower onset of action.

Bupivacaine epidural bolus doses at a concentration of 0.125% produce adequate postoperative analgesia in many clinical settings with only mild motor deficits.[65] Continuous epidural infusions of bupivacaine as dilute as 0.0625% to 0.1% are useful for labor epidural analgesia, especially when administered in combination with opioids and epinephrine. Bupivacaine 0.25% may be used for more intense analgesia (particularly during combined epidural-general anesthesia cases) with moderate degrees of motor block. Bupivacaine at concentrations of 0.5% to 0.75% is associated with a more profound degree of motor block, and surgical anesthesia. It should be emphasized that although high concentrations of local anesthetics may be appropriate for episodic bolus dosing for surgery, these concentrations (i.e., 0.25% for bupivacaine) should not be first choice for continuous epidural infusions. In some patients, increasing the local anesthetic dose or addition of adjuvants such as epinephrine and lipophilic opioids is necessary to achieve adequate block intensity. Bolus injections produce much more cephalocaudad spread than continuous infusions do. When concentrated bupivacaine solutions are used for infusions, they have the potential for excessive local effect with an associated risk for unwanted and very prolonged motor blockade. Drugs available for subarachnoid administration are shown in Table 29.8. Bupivacaine is widely used as a spinal anesthetic, either as a hyperbaric solution at a concentration of 0.75% with 8.25% dextrose or by using the nearly isobaric (though slightly hypobaric) 0.5% solution. Intrathecal bupivacaine possesses an anesthetic profile similar to that of tetracaine.[66]

The addition of vasoconstrictors may prolong the duration of spinal anesthesia; for example, the addition of 0.2 to 0.3 mg of epinephrine to lidocaine, tetracaine, or bupivacaine solutions will produce a 50% or greater increase in duration.[67,68] The duration of spinal anesthesia produced by tetracaine can also be increased to a similar extent by adding 1 to 5 μg of phenylephrine. The addition of epinephrine to bupivacaine or lidocaine may be more effective in prolonging the duration of spinal anesthesia in lumbosacral segments than in thoracic segments.

TOPICAL ANESTHESIA

A number of local anesthetic formulations are available for topical anesthesia (Table 29.9), lidocaine, dibucaine, tetracaine, and benzocaine being the drugs used most commonly. In general, these preparations provide effective but relatively short durations of analgesia when applied to mucous membranes or abraded skin. Their efficacy is determined by drug form, melting point, concentration, and skin permeability.[69] Lidocaine and tetracaine sprays are commonly used for endotracheal anesthesia before intubation or for mucosal analgesia for bronchoscopy or esophagoscopy.

A variety of topical local anesthetic formulations have been developed to penetrate intact skin. EMLA, which is a eutectic mixture of 2.5% lidocaine base and 2.5% prilocaine base, is widely used for venipuncture, intravenous cannulation, skin grafting, and a range of other uses, including circumcision.[70] This preparation must be applied under an occlusive bandage for 45 to 60 minutes to obtain effective

TABLE 29.7 Epidural Anesthesia

Drug With Epinephrine (1:200,000)	Usual Concentration (%)	Usual Volume (mL)	Maximum Dose (mg) Without/With Epinephrine	Usual Onset (min)	Usual Duration (min)
Chloroprocaine	2-3	15-30	700/900	5-15	30-90
Lidocaine	1-2	15-30	350/500	5-15	
Mepivacaine	1-2	15-30	350/500	5-15	60-180
Prilocaine	1-3	15-30	350/500	5-15	
Bupivacaine	0.25-0.5	15-30	175/225	15-20	180-350
Levobupivacaine	0.25-0.75	15-30	200/250	15-20	180-350
Ropivacaine	0.2-0.75	15-30	200/250	15-20	180-350

See also Chapter 45. Doses are for a 70-kg adult receiving epinephrine-containing solutions. Doses should be reduced for children, for patients with specific risk factors, and for specific catheter tip locations (e.g., upper thoracic).

TABLE 29.8 Spinal Anesthesia

Drug	Usual Concentration (%)	Usual Volume (mL)	Total Dose (mg)	Baricity	Glucose Concentration (%)	Usual Duration (min)
Procaine	10.0	1-2	100-200	Hyperbaric	5.0	30-60
Lidocaine	1.5, 5.0	1-2	30-100	Hyperbaric	7.5	30-90
Mepivacaine	4.0	1-2	40-80	Hyperbaric	9.0	30-90
Tetracaine	0.25-1.0	1-4	5-20	Hyperbaric	5.0	90-200
	0.25	2-6	5-20	Hypobaric		90-200
	1.0	1-2	5-20	Isobaric		90-200
Dibucaine	0.25	1-2	2.5-5.0	Hyperbaric	5.0	90-200
	0.5	1-2	5-10	Isobaric		90-200
	0.06	5-20	3-12	Hypobaric		90-200
Bupivacaine	0.5	3-4	15-20	Isobaric		90-200
	0.75	2-3	15-20	Hyperbaric	8.25	90-200
Levobupivacaine	0.5	3-4	15-20	Isobaric		90-200
	0.75	2-3	15-20	Hyperbaric		90-200
Ropivacaine	0.5	3-4	15-20	Isobaric		90-200
	0.75	2-3	15-20	Hyperbaric		90-200

Doses are for a 70-kg adult. Dosing may be reduced during pregnancy and with advancing age. Pediatric dosing is detailed in Chapter 76.

TABLE 29.9 Various Preparations Intended for Topical Anesthesia

Anesthetic Ingredient	Concentration (%)	Pharmaceutical Application Form	Intended Area of Use
Benzocaine	1-5	Cream	Skin and mucous membrane
	20	Ointment	Skin and mucous membrane
	20	Aerosol	Skin and mucous membrane
Cocaine	4	Solution	Ear, nose, throat
Dibucaine	0.25-1	Cream	Skin
	0.25-1	Ointment	Skin
	0.25-1	Aerosol	Skin
	0.25	Solution	Ear
	2.5	Suppositories	Rectum
Cyclomine	0.5-1	Solution	Skin, oropharynx, tracheobronchial tree, urethra, rectum
Lidocaine	2-4	Solution	Oropharynx, tracheobronchial tree, nose
	2	Jelly	Urethra
	2.5-5	Ointment	Skin, mucous membrane, rectum
	2	Viscous	Oropharynx
	10	Suppositories	Rectum
	10	Aerosol	Gingival mucosa
Tetracaine	0.5-1	Ointment	Skin, rectum, mucous membrane
	0.5-1	Cream	Skin, rectum, mucous membrane
	0.25-1	Solution	Nose, tracheobronchial tree
EMLA	Lidocaine, 2.5 Prilocaine, 2.5	Cream	Intact skin
TAC	Tetracaine, 0.5 Epinephrine, 1:200,000 Cocaine, 11.8	Solution	Cut skin
LET	Lidocaine, 4% Epinephrine, 1:20,000 Tetracaine, 0.5%	Solution	Cut skin

EMLA, Eutectic mixture of lidocaine and prilocaine; *LET,* lidocaine-epinephrine-tetracaine; *TAC,* tetracaine-epinephrine-cocaine.
From Covino B, Vassallo H. *Local Anesthetics: Mechanisms of Action and Clinical Use*. Orlando, FL: Grune and Stratton; 1976.

cutaneous anesthesia; longer application times increase the depth and reliability of skin analgesia. EMLA appears to be quite safe in neonates, and methemoglobinemia with the use of prilocaine is exceedingly uncommon. EMLA is more effective for newborn circumcision than placebo is but less effective than dorsal penile nerve block.[70,71] Several alternative topical local anesthetic formulations also are in use, including tetracaine gel[72] and liposomal lidocaine.[73] Physical methods to accelerate local anesthetic transit across skin, including iontophoresis, local heating, electroporation, and a variety of forms of needleless pressure injection, may lead to more rapid onset of cutaneous analgesia.[74] Synera (originally studied as S-Caine) is a formulation of lidocaine and tetracaine that was developed with a heating element (activated by opening the package to initiate an oxygen-dependent exothermic reaction). This formulation has a rapid onset and evokes vasodilatation.[75]

Topical anesthesia through cut skin is commonly used in pediatric emergency departments for liquid application into lacerations that require suturing. Historically, this had been provided by a mixture of tetracaine, epinephrine (adrenaline), and cocaine, known as TAC. TAC is ineffective through intact skin; in contrast, its rapid absorption from mucosal surfaces can lead to toxic, even fatal reactions. Another potential substance is ELA-max, a liposomal formulation of lidocaine which is useful for cuts or abrasions.[76] Lastly, Lidoderm patches have been in use for the topical treatment of postherpetic neuralgia.[77]

Because of concerns regarding cocaine toxicity and the potential for diversion and abuse, cocaine-free topical preparations are strongly recommended, and alternatives such as the combination of an α_1-adrenergic agonist (oxymetazoline or phenylephrine) and a local anesthetic such as 2% to 4% lidocaine should be used, with more dilute solutions being recommended for infants and children.

TUMESCENT ANESTHESIA

A technique of local anesthesia most commonly used by plastic surgeons during liposuction procedures involves the subcutaneous injection of large volumes of dilute local anesthetic in combination with epinephrine and other agents. Total doses of lidocaine ranging from 35 to 55 mg/kg have been reported to produce safe plasma concentrations around or below 5 μg/mL, but notably, these may only peak up to 20 hours after infusion, depending on the site of infiltration.[78] Despite these seemingly huge doses, very good safety outcomes have been reported in several case series.[79] Conversely, there have been several case series of cardiac arrest and death during plastic surgical procedures in patients with multiple risk factors. Here high local anesthetic concentrations and concomitant use of sedatives may have contributed to the patients' instability and deterioration.[80] Factors governing uptake and clearance from this method of local anesthetic delivery deserve further study.

SYSTEMIC LOCAL ANESTHETICS FOR POSTOPERATIVE PAIN AND NEUROPATHIC PAIN

Systemic lidocaine has been extensively investigated over the past 10 years for its potential to inhibit G protein-coupled receptors, especially those of the Gq11 subfamily. Systemic local anesthetics have a strong antiinflammatory effect, but their application has only been shown to be of clinical significance in visceral surgery where they decrease inflammation and pain, and speed recovery when compared to placebo.[81]

A broad variety of local anesthetics, antiarrhythmics, anticonvulsants, and other Na^+ channel blockers are administered intravenously, orally, or both, to relieve a number of forms of chronic neuropathic pain.[82] Clinical results are variable.[83] Although successful responses from intravenous lidocaine are often taken as a positive indication for oral mexiletine, some patients find mexiletine difficult to tolerate. When the signs of neuropathic pain are reversed by lidocaine infusion, normal nociception and other sensory modalities are unaffected, suggesting that the neurophysiologic correlate of the disease has an unusually high susceptibility to these drugs, present in plasma at concentrations 50 to 100 times lower than that required to block normal impulses in peripheral fibers. Laboratory studies suggest that ectopic impulse activity arising at a site of injury or elsewhere, such as the dorsal root ganglion, contributes to the neuropathic pain and that such impulses are particularly sensitive to use-dependent Na^+ channel blockers. It is noteworthy that relief of preexisting neuropathic pain, both clinically and in animal models,[84] can in some cases persist for days, weeks, or months after a single intravenous infusion of drug (e.g., lidocaine), far beyond the lifetime of the drug in vivo or any nerve block that it might affect. The mechanism of this remarkable action remains a mystery. Intuitively, this should be especially true for hereditary syndromes featuring gain-of-function mutations at the sodium channel, such as primary erythromelalgia and recent clinical experience and translational experiments have confirmed that mexiletine has the potential to normalize sodium currents in one specific mutation associated with erythromelalgia.[85]

Pharmacokinetics

The concentration of local anesthetics in blood is determined by the amount injected, the rate of absorption from the site of injection, the rate of tissue distribution, and the rate of biotransformation and excretion of the specific drug.[79,80] Patient-related factors such as age, cardiovascular status, and hepatic function influence the physiologic disposition and resultant blood concentration of local anesthetics.

ABSORPTION

The systemic absorption of local anesthetics is determined by the site of injection, dosage and volume, addition of a vasoconstrictor agent, and the pharmacologic profile of the agent itself.[86,87] Comparison of the blood concentration of local anesthetics after various routes of administration reveals that the anesthetic drug level is highest after intercostal nerve blockade, followed in order of decreasing concentration by injection into the caudal epidural space, lumbar epidural space, brachial plexus, and subcutaneous tissue. When a local anesthetic solution is exposed to an area of greater vascularity, a greater rate and degree of absorption occur. This relationship is of clinical significance because use of a fixed dose of a local anesthetic agent may be potentially toxic in one area of administration but not in others, and in one patient with specific physiology, but not in others. For example, the use of 400 mg of lidocaine without epinephrine for an intercostal nerve block results in an average peak venous plasma level of approximately 7 μg/mL, which is sufficiently high to cause symptoms of central nervous system (CNS) toxicity in some patients. By comparison, this same dose of lidocaine used for a brachial plexus block yields a mean maximum blood level of approximately 3 μg/mL, which is rarely associated with signs of toxicity.

The maximum blood concentration of local anesthetic drugs is related to the total dose of drug administered for any particular site of administration. For most drugs there is a proportionality between the amount of drug administered and the resultant peak anesthetic blood concentration. Epinephrine decreases the rate of vascular absorption of certain agents from various sites of administration and thus lowers their potential systemic toxicity. A 5-μg/mL concentration of epinephrine (1:200,000) significantly reduces the peak blood levels of lidocaine and mepivacaine irrespective of the site of administration. Resorption of local anesthetics follows a biphasic pattern, with an initial fast peak reflecting the fluid phase and later a slower second peak corresponding to resorption from the lipid compartment.[88] The addition of epinephrine to local anesthetic solutions slows the first phase.[89] The net clinical effect is a more profound block, and lower systemic levels.[90]

DISTRIBUTION

The systemic distribution of local anesthetics in many settings can be described sufficiently by a two-compartment model.[91] The rapid disappearance phase is believed to be related to uptake by rapidly equilibrating tissues (i.e., tissues that have high vascular perfusion). The slower phase of disappearance from blood is mainly a function of the particular compound.[86] Local anesthetic drugs are distributed throughout all body tissues, but the relative concentration in different tissues varies. In general, more highly perfused organs show higher concentrations of local anesthetic drug than less well perfused organs do. The primary extraction takes place in the liver, but local anesthetics are also rapidly extracted by lung tissue.[92,93]

BIOTRANSFORMATION AND EXCRETION

The pattern of metabolism of local anesthetic agents varies according to their chemical classification. The esters, or procaine-like drugs, undergo hydrolysis in plasma by the pseudocholinesterase enzymes; clearance of chloroprocaine is especially rapid.[94,95] The aminoamide drugs undergo enzymatic degradation primarily in the liver. Lidocaine is metabolized somewhat more rapidly than mepivacaine, which in turn is more rapidly metabolized than bupivacaine.[71,96,97] Excretion of the metabolites of amide-type local anesthetics occurs via the kidney. Less than 5% of the unchanged drug is excreted via the kidney into urine.

PHARMACOKINETIC ALTERATIONS BY PATIENT STATUS

Patient age may influence the physiologic disposition of local anesthetics. The half-life of lidocaine after intravenous administration averaged 80 minutes in human volunteers varying in age from 22 to 26 years, whereas volunteers 61 to 71 years of age demonstrated a significantly prolonged lidocaine half-life that averaged 138 minutes.[98]

Newborn infants have immature hepatic enzyme systems and hence prolonged elimination of lidocaine, bupivacaine, and ropivacaine.[99] Bupivacaine, for example, has a terminal elimination half-life in adults that averages around 3.5 hours. In neonates and some younger infants, terminal elimination half-lives may be as long as 8 to 12 hours. Prolonged elimination is particularly an issue for continuous infusions of local anesthetics in infants, and seizures have been associated with high bupivacaine infusion rates.[100] Based on analysis of these cases, a maximum infusion rate of 0.4 mg/kg/h for prolonged bupivacaine infusions has been proposed for children and adults, whereas prolonged infusion rates for neonates and young infants should not exceed 0.2 mg/kg/h.[101] Even at 0.2 mg/kg/h, plasma bupivacaine concentrations were found to be rising toward a toxic range in some younger infants after 48 hours.[102] Similarly, prolonged lidocaine infusions in neonates should not exceed 0.8 mg/kg/h. The potential for toxicity with lidocaine infusions in neonates is also increased by the accumulation of its principal metabolite, monoethylglycinexylidide (MEGX), which can cause seizures. Chloroprocaine may offer unique advantages for epidural infusion in neonates because it is rapidly cleared from plasma, even in preterm neonates.[103]

Decreased hepatic blood flow or impaired hepatic enzyme function can produce a substantial elevation of blood levels of the aminoamide local anesthetics. An average lidocaine half-life of 1.5 hours was reported in volunteers with normal hepatic function, whereas patients with liver disease demonstrated an average half-life of 5.0 hours. The rate of disappearance of lidocaine from blood has also been shown to be markedly prolonged in patients with congestive heart failure.[104]

In some patients CNS depression is seen without a preceding excitatory phase, particularly if other CNS depressant drugs had been administered.

Toxicity

Local anesthetic drugs are relatively safe if administered in an appropriate dosage and in the correct anatomic location. However, systemic and localized toxic reactions can occur, usually as a result of accidental intravascular or intrathecal injection or administration of an excessive dose. In addition, specific adverse effects are associated with the use of certain drugs, such as allergic reactions to the aminoester drugs and methemoglobinemia after the use of prilocaine.

SYSTEMIC TOXICITY

Systemic reactions to local anesthetics primarily involve the CNS and the cardiovascular system. In general, the CNS is more susceptible to the actions of systemic local anesthetics than the cardiovascular system, and thus the dose or blood level of local anesthetic required to produce CNS toxicity is usually lower than that resulting in circulatory collapse. However, a recent review of 93 cases showed that the symptoms encountered initially vary widely; and only 60% of patients actually exhibit the classic sequence of toxic events from minor CNS symptoms (e.g., perioral tingling, metallic taste, tinnitus), followed by major CNS symptoms (seizures) and cardiovascular collapse (CC).[105] Overall, the incidence of systemic toxicity following regional anesthesia is estimated at 1:1000 for nerve stimulator-guided blockade, and 1:1600 for ultrasound-guided regional anesthesia.[106]

Central Nervous System Toxicity

The initial symptoms of local anesthetic-induced CNS toxicity are feelings of lightheadedness and dizziness followed frequently by visual and auditory disturbances such as difficulty focusing and tinnitus. Other subjective CNS symptoms include disorientation and occasional feelings of drowsiness. Objective signs of initial CNS toxicity are usually excitatory in nature and include shivering, muscular twitching, and tremors initially involving muscles of the face and distal parts of the extremities. Ultimately, generalized convulsions of a tonic-clonic nature occur. If a sufficiently large dose or rapid intravenous injection of a local anesthetic is administered, the initial signs of CNS excitation are rapidly followed by a state of generalized CNS depression. Seizure activity ceases, and respiratory depression and ultimately respiratory arrest may occur. CNS excitation may be the result of an initial blockade of inhibitory pathways in the cerebral cortex by local anesthetic drugs but can also result from the net stimulation of release of glutamate, an excitatory amino acid neurotransmitter. Blockade of inhibitory pathways allows facilitatory neurons to function in an unopposed fashion, which results in an increase in excitatory activity leading to convulsions. A further increase in the dose of local anesthetic leads to inhibition of activity of both the inhibitory and facilitatory circuits, which results in a generalized state of CNS depression.

In general, a correlation exists between potency of the local anesthetic and intravenous CNS toxicity.[107] Convulsions caused by an inadvertent intravenous bolus of local anesthetic can generally be terminated by small intravenous doses of a benzodiazepine, such as midazolam, or by small intravenous doses of propofol. While propofol is faster acting, large doses should be avoided, especially in patients with hemodynamic instability.[108] Respiratory or metabolic acidosis increases the risks for CNS toxicity from local anesthetics.[109] Elevated $PaCO_2$ enhances cerebral blood flow and thus the anesthetic is delivered more rapidly to the brain. In addition, diffusion of carbon dioxide into neuronal cells decreases intracellular pH, which facilitates conversion of the base form of the drugs to the cationic form. The cationic form does not diffuse well across the nerve membrane, so ion trapping will occur, which will increase the apparent CNS toxicity of local anesthetics. Hypercapnia and acidosis also decrease the plasma protein binding of local anesthetic agents.[110] Accordingly, normocapnia should be targeted during episodes of local anesthetic systemic toxicity.

The clinical implication of this effect of hypercapnia and acidosis on toxicity deserves emphasis. Seizures produce hypoventilation and a combined respiratory and metabolic acidosis, which further exacerbates the CNS toxicity. In the setting of local anesthetic toxic reactions, it is essential to provide prompt assisted ventilation and circulatory support as needed to prevent or correct hypercapnia and acidosis and to prevent or correct hypoxemia, which also exacerbates CNS toxicity. Based on the preceding discussion, it should be apparent that clinicians performing major conduction blockade should make a routine practice of having the following ready at hand: monitoring equipment; an oxygen tank or wall oxygen outlet; rescue airway equipment; and drugs to terminate convulsions, such as midazolam, thiopental, or propofol.

Cardiovascular System Toxicity

Local anesthetics can exert direct actions on both the heart and peripheral blood vessels, as well as indirect actions on the circulation by blockade of sympathetic or parasympathetic efferent activity.

Direct Cardiac Effects. The main mechanisms of local anesthetic toxicity are blockades of cardiac sodium channels leading to negative inotropy and arrhythmia. Local anesthetics act directly by decreasing the conduction in Purkinje fibers and cardiomyocytes by prolonging the recovery time. Other facets of local anesthetic toxicity include inhibition of fatty acid metabolism, interference with calcium homeostasis, and disruption of the mitochondrial respiratory chain.[111] The primary cardiac electrophysiologic effect of local anesthetics is a decrease in the rate of depolarization in the fast conducting tissues of Purkinje fibers and ventricular muscle.[112] This reduction in rate is believed to be due to a decrease in the availability of fast sodium channels in cardiac membranes. Action potential duration and the effective refractory period are also decreased by local anesthetics. However, this effect is dose-dependent and substance-specific. Specifically, electrophysiologic studies have shown that high blood levels of local anesthetics will prolong conduction time through various parts of the heart, as indicated on the electrocardiogram (ECG) by an increase in the PR interval and duration of the QRS complex. Extremely high concentrations of local anesthetics depress spontaneous pacemaker activity in the sinus node, thereby resulting in sinus bradycardia and sinus arrest. Also, the electrophysiologic effects of various agents differ qualitatively. Bupivacaine depresses the rapid phase of depolarization (V_{max}) in Purkinje fibers and ventricular muscle to a greater extent than lidocaine does. In addition, the rate of recovery from a use-dependent block is slower in bupivacaine-treated papillary muscles than in lidocaine-treated muscles. This slow rate of recovery results in incomplete restoration of Na^+ channel availability between action potentials, particularly at high heart rates. These differential effects of lidocaine and bupivacaine have been advanced as explanations of the antiarrhythmic properties of lidocaine versus the arrhythmogenic potential of bupivacaine. All local anesthetics exert dose-dependent negative inotropic action on cardiac muscle; the depression of cardiac contractility is roughly proportional to conduction blocking potency. Thus bupivacaine and tetracaine are more potent cardio depressants than is lidocaine. Local anesthetics may depress myocardial contractility by affecting calcium influx and triggered release from the sarcoplasmic reticulum,[113] as well as by inhibiting cardiac sarcolemmal Ca^{2+} currents and Na^+ currents. Lastly, mitochondrial metabolism is inhibited by bupivacaine, and, to a lesser extent, other long-acting local anesthetics such as ropivacaine,[114] while the effect of lidocaine is smaller.

Direct Peripheral Vascular Effects. Local anesthetics exert biphasic effects on peripheral vascular smooth muscle.[103] Low concentrations of lidocaine and bupivacaine produced vasoconstriction in the cremaster muscle of rats, whereas high concentrations produced vasodilation in both isolated tissue models and in vivo. Cocaine is the only local anesthetic that consistently causes vasoconstriction at all concentrations because of its ability to inhibit the uptake of norepinephrine by premotor neurons and thus to potentiate neurogenic vasoconstriction.

COMPARATIVE CARDIOVASCULAR TOXICITY

All local anesthetics, but especially bupivacaine, can cause rapid and profound cardiovascular depression. The cardiotoxicity of bupivacaine appears to differ from that of lidocaine in the following manner:

1. The ratio of the dosage required for irreversible CC and the dosage that will produce CNS toxicity (convulsions; i.e., the CC/CNS ratio) is lower for bupivacaine and etidocaine than for lidocaine.[115]
2. Ventricular arrhythmias and fatal ventricular fibrillation may occur more often after the rapid intravenous administration of a large dose of bupivacaine but far less frequently with lidocaine. The CNS effects of local anesthetics may contribute to the generation of arrhythmias.
3. A pregnant patient may be more sensitive to the cardiotoxic effects of bupivacaine than a nonpregnant animal or patient.[116] Consequently, the 0.75% solution of bupivacaine is no longer recommended for use in obstetric anesthesia in the United States.
4. Cardiac resuscitation is more difficult after bupivacaine-induced CC, and acidosis and hypoxia markedly potentiate the cardiotoxicity of bupivacaine.[117] Conversely, Intralipid is believed to be most effective in bupivacaine-induced toxicity. Despite the experimental or clinical anecdotal use of many different resuscitation drugs in the setting of bupivacaine overdose, current guidelines focus on standard cardiopulmonary resuscitation, albeit with titration rather than fixed doses of epinephrine, early administration of lipid emulsion, and avoidance of propofol in settings of hemodynamic instability.[108] Bupivacaine-induced ventricular arrhythmias should not be treated with vasopressin, calcium channel blockers, β-blockers, or other local anesthetics with antiarrhythmic potential (such as lidocaine).[118]

Pharmacokinetic studies have estimated that Intralipid decreases cardiac bupivacaine concentration by 11% within 3 minutes of administration, and cerebral bupivacaine content by 18% within 15 minutes.[119] Even though these findings are theoretical, they underline the notion that Intralipid should not be considered an antidote with full antagonistic properties. Rather, limited evidence suggests that it will considerably reduce the bupivacaine concentration in target organs, most likely improve metabolism, and potentially have direct beneficial effects at the sodium channel. Intralipid is a valuable contribution to, but not a substitute for, careful and meticulous conduct of regional anesthesia.[120]

The clinical implications for cardiac resuscitation after intravascular injection or overdose of local anesthetic are the following:

1. No medications are uniformly effective in facilitating resuscitation from bupivacaine-induced cardiac arrest or severe ventricular tachycardia (despite our recommendations regarding Intralipid later). Basic principles of cardiopulmonary resuscitation should be emphasized first, including attention to securing the airway, providing oxygenation and ventilation, and performing chest compressions as indicated.
2. Because resuscitation after local anesthetic-induced circulatory collapse is difficult, prevention of massive intravascular injection or excessive dosing is crucial.
3. Negative aspiration of the syringe does not always exclude intravascular placement. Incremental, fractionated dosing should be the rule for all patients undergoing major conduction blockade. Even though changes on the ECG are not present in all cases before circulatory collapse, they can often be seen, and continuous attention to the ECG (including changes in QRS and T-wave morphology, rate, rhythm, or ectopy) may be lifesaving by terminating injection before a cardiac arrest occurs.
4. Based on animal studies[121] and a growing number of human case reports, hospitals and clinics that perform major conduction blockade or large volume infiltration blockade should keep available for emergency use a supply of lipid emulsion such as Intralipid 20%. If a patient experiences profound cardiovascular depression or circulatory arrest after the administration of bupivacaine, ropivacaine, or by extrapolation, other local anesthetics, then along with initiation of basic life support and the ACLS protocol, a rapid bolus of Intralipid 20%, 1.5 mL/kg (approximately 100 mL in adults) is recommended, followed if necessary by an infusion of 0.25 mL/kg/min over the next 10 minutes.

Chiral Local Anesthetics: Ropivacaine and Levobupivacaine

Commercial bupivacaine is a racemic mixture of *(R)*- and *(S)*-stereoisomers. In response to the problem of cardiovascular toxicity as a result of accidental intravenous injection of bupivacaine, single enantiomers were developed in the hope that they would be potentially safer. Ropivacaine (Naropin)[122] and levo-*(S)*-bupivacaine (Chirocaine)[123] were formulated to exploit this stereoselectivity. Ropivacaine is a single *(S)*-stereoisomer that differs from levobupivacaine in the substitution of a propyl for the butyl group on the piperidine ring (see Fig. 29.2). With these designed changes in molecular structure, it was hoped that ropivacaine and levobupivacaine would be less intrinsically cardiotoxic. Conversely, it appears that the *(S)*-enantiomers of mepivacaine and bupivacaine are metabolized by the liver more slowly than the corresponding *(R)*-enantiomers, which would lead to somewhat greater systemic accumulation with prolonged infusions.

The very slow reversal of Na^+ channel blockade after a cardiac action potential, which is a hallmark of bupivacaine, is considerably faster with ropivacaine. In addition to these electrical differences, the negative inotropic potency of ropivacaine on isolated cardiac tissue appears to be considerably less than that of bupivacaine. Both electrical and mechanical differences in the toxic profiles may arise from the selective inhibition of Ca^{2+} currents by bupivacaine.

Do the data support the claim of a greater therapeutic index for ropivacaine than bupivacaine, particularly with regard to cardiotoxicity? In clinical studies comparing potencies of ropivacaine and bupivacaine administered for brachial plexus[124] or lumbar epidural block,[125] the anesthetic profiles of the drugs were almost identical. A third exemplary study comparing lumbar epidural 0.5% bupivacaine with 0.75% ropivacaine also found no significant differences in motor or sensory effects between the drugs at these different concentrations.[126] Overall, it appears that ropivacaine is slightly less potent than bupivacaine (1:1.3 to 1:1.5) for regional anesthesia. In some laboratory animal studies and in some human studies, ropivacaine also produced blocks of shorter duration than those induced by bupivacaine. Other studies in animals and humans have found equal durations of sensory and motor block for the two drugs.

At the projected equipotent doses for nerve block, are the drugs equally toxic? The overall impression is that ropivacaine is less cardiotoxic than bupivacaine. Studies in animals have generally found that bupivacaine more readily produces conduction disturbances, cardiac collapse, or ventricular fibrillation than ropivacaine does and that aggressive cardiac resuscitation after an intentional intravenous bolus in dogs leads to effective reversal of the toxic effects far more frequently with ropivacaine than with bupivacaine.[127]

The greater safety of ropivacaine than bupivacaine may be related both to the reduced toxicity of the single *(S)*-isomer and to the difference between the propyl- and butyl-*N*-piperidine substituent. In contrast to bupivacaine, the cardiotoxic profile of ropivacaine in pregnant ewes is the same as the corresponding profile in nonpregnant ewes.[128]

Levobupivacaine has been studied in a range of clinical settings and sites of administration. Although a number of publications have compared levobupivacaine with racemic bupivacaine and ropivacaine,[129,130] conclusions differ among studies regarding the relative potency and duration of block of these three drugs at different sites of administration with respect to sensory and motor end points. Clinicians should note that levobupivacaine is formulated as a weight percentage with regard to its free base content, whereas the weight percentage of most other local anesthetics is calculated on the basis of the hydrochloride salt.[131]

Acidosis and Hypoxia

As with CNS toxicity, hypercapnia, acidosis, and hypoxia potentiate the negative chronotropic and inotropic actions of lidocaine and bupivacaine in isolated cardiac tissue, and the combination of hypoxia and acidosis markedly potentiates the cardiodepressant effects of bupivacaine.[132] Hypoxia and acidosis also increased the frequency of cardiac arrhythmias and the mortality rate in sheep after the intravenous administration of bupivacaine. Hypercapnia, acidosis, and hypoxia occur very rapidly in some patients after seizure activity caused by the rapid accidental intravascular injection of local anesthetic agents.[133] Thus the cardiovascular depression observed in some patients after the accidental intravenous injection of bupivacaine may be related in part to the effect of seizures producing acidosis and hypoxia and thereby leading to an exacerbation of bupivacaine's intrinsic cardiotoxicity.

Indirect Cardiovascular Effects

High levels of spinal or epidural blockade can produce severe hypotension. A follow-up study of closed claims of patients who suffered perioperative cardiac arrest confirmed previous reports of a series of cardiac arrests involving generally healthy patients undergoing spinal or epidural anesthesia.[134] These events frequently occurred in conjunction with high dermatomal levels of blockade, liberal use of sedatives, and progression to cardiac arrest after a period of hypotension accompanied by bradycardia, often involving delays in recognition of the problem, delays in instituting airway support (particularly in sedated patients), and delays in administration of direct-acting combined α- and β-adrenergic agonists, such as epinephrine. Whereas mild to moderate degrees of hypotension generally respond well to indirect-acting sympathomimetics such as ephedrine or incremental dosing of phenylephrine, the combination of severe hypotension and severe bradycardia under spinal anesthesia should in most clinical settings be treated promptly with incremental dosing of epinephrine, initially at doses of 0.1 to 1 μg/kg.

METHEMOGLOBINEMIA

A unique systemic side effect associated with a specific local anesthetic is the development of methemoglobinemia after the administration of large doses of prilocaine.[135] In general, 600-mg doses are required for the development of clinically significant levels of methemoglobinemia in adults. Hepatic metabolism of prilocaine generates *O*-toluidine, which oxidizes hemoglobin to methemoglobin. Methemoglobinemia, if severe, may be treated by the intravenous administration of methylene blue. Standard dosing of the topical local anesthetic EMLA (a mixture of lidocaine and prilocaine) in term newborns produced minimal amounts of methemoglobin, and EMLA, if dosed appropriately, should be regarded as very safe in the great majority of newborns. Risk may be increased in newborns with rare metabolic disorders or after the concomitant administration of other drugs that impair reduction of methemoglobin.

ALLERGIES

Even though patients receiving local anesthetics may experience a range of local and systemic symptoms, prospective studies indicate that very few of these reactions are truly confirmed as allergic reactions.[136,137] Aminoester drugs such as procaine may produce allergic-type reactions more commonly than do the aminoamides, although even with aminoesters, the vast majority of reactions are not allergic. Aminoesters, unlike aminoamides, are derivatives of *p*-aminobenzoic acid, which is known to be allergenic. Some aminoamide solutions may contain a preservative, methylparaben, whose chemical structure is similar to that of *p*-aminobenzoic acid, but for most aminoamides, preservative-free solutions are available.[138] Contamination of vials with latex antigen has been suspected in some allergic reactions, although it has been difficult to confirm. In the very rare patient for whom confirmed allergy to both aminoamides and aminoesters precludes their use for spinal anesthesia, meperidine can be considered as an alternative.[128]

LOCAL TISSUE TOXICITY

All the clinically used aminoamide and aminoester local anesthetics can produce direct toxicity to nerves if they achieve sufficiently high intraneural concentrations.[139] Conversely, in the great majority of clinical applications, no damage to nerves occurs. Although local anesthetics are usually packaged and injected at concentrations well above their physiologically effective range, in the process of delivery they are generally diluted sufficiently that no harm is done. If such dilution does not occur, however, long-term or permanent neural deficits do result. Thus the application of 5% (200 mM) lidocaine in viscous, dense solutions through narrow intrathecal catheters had been associated with a high frequency of transient or longer-term radicular symptoms or even cauda equina syndrome.[140] Laboratory investigations have shown that such high concentrations of local anesthetics alone applied directly to bare nerve fibers produce an irreversible conduction block in less than 5 minutes.[141] Clinicians should be aware that the concentrations of formulated local anesthetic solutions are neurotoxic per se and that their "natural" dilution, which occurs in situ or in tissue, is essential for safe use.

If cauda equina syndrome was considered one catastrophic end of the spectrum, the opposite side would be transient neurologic syndrome, a temporary radicular irritation thought to be caused by local anesthetic application and influenced by patient positioning.[142] Single-shot spinal anesthesia with commonly recommended doses and concentrations of many different local anesthetics can produce more limited and transient neurologic symptoms (back pain, paresthesias, radicular pain, or hypesthesia).[143] Some studies and systematic reviews have found that mepivacaine and lidocaine at a range of dilutions cause more frequent symptoms than do bupivacaine and prilocaine.[144] The risk of transient neurologic symptoms after spinal anesthesia was not diminished by dilution of lidocaine from 5% to either 1% or 2%. Differences in study design, method of questioning, and criteria for inclusion may be partially responsible for differences in the prevalence of radicular sequelae in various studies. Despite these differences in study design, a meta-analysis concluded that the pooled relative risk for transient neurologic symptoms after spinal anesthesia with lidocaine was 6.7-fold higher than with bupivacaine and 5.5-fold higher than with prilocaine.[144] The addition of vasoconstrictors to local anesthetic solutions has been reported to potentially increase risk,[145] but within the limits of current dosing, neuraxial administration of vasoconstrictors as an adjuvant seems to be safe.[146] Neurotoxicity appears to be unrelated to conduction block per se, because STX, neosaxitoxin, and tetrodotoxin, highly potent blockers of sodium channels, can produce intense conduction blockade without histologic or behavioral signs of nerve injury.[147]

Skeletal muscle changes have been observed after the injection of local anesthetic agents such as lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine.[148] In general, the more potent, longer-acting agents bupivacaine and etidocaine appear to cause more localized skeletal muscle damage than do the less potent, shorter-acting agents lidocaine and prilocaine. This effect on skeletal muscle, to the best of our current knowledge, is reversible due to the regenerative potential of skeletal muscle and the comparatively small area of the muscle affected, which is why it is often clinically inapparent.

Development of Prolonged-Duration and Sensory- or Nociceptive-Selective Local Anesthetics

Several methods for producing long-duration nerve blockade are under investigation. First, there have been efforts to use readily available drugs such as tricyclic antidepressants[149,150] or quaternary local anesthetic derivatives as novel local anesthetics,[151] but these efforts have consistently been hampered by concerns over neurotoxicity.

SLOW-RELEASE FORMULATIONS

Liposomal encapsulation can prolong nerve blockade, depending on the dose and the physical properties of the liposome (surface charge, size, lamellar structure).[141-143] This mode of action has been investigated for decades but the clinical introduction has only been recent. Liposomal bupivacaine (Exparel) has been licensed for infiltration analgesia[152] but its dose-response for blockade of peripheral nerves is less clear.[153] A recent study showed potential benefits when combining Exparel with bupivacaine for interscalene block,[154] and the Food and Drug Administration has moved to expand Exparel licensing to select nerve block indications. Despite strong basic science data, the clinical benefit of these formulations, especially for nerve blockade, and when compared to plain long-acting local anesthetics, is not as convincing as one would hope. Other modes of slow-release are embedding in bone wax, polylactic acid, polyglycolic acid, fatty-acid-based biodegradable polymers, and proliposomal formulations.[7] Finally, another variant of slow-release formulations is photo-triggered on-demand release.

SITE 1 BLOCKERS

Prolonged-duration local anesthesia also appears to be feasible with the use of site 1 sodium channel blockers.[148] The site 1 blocker neosaxitoxin has been used in humans in phase 1 and phase 2 clinical trials.[149-151] A combination of site 1 toxins with either local anesthetics or adrenergics results in prolongation of blockade and improvement in the therapeutic index.[155] Theoretically attractive features of site 1 toxins include their apparent lack of local tissue toxicity on nerves[137] or muscles[152] and their minimal cardiotoxicity.[153]

TARGETING OF SPECIFIC SODIUM CHANNEL ISOFORMS

Coming back to the nine different subtypes of sodium channels, research efforts have been directed at blocking specific isoforms thought to be of particular relevance for defined pain conditions. The Nav1.7 subtype, for example, has been linked to somatic pain, and to hereditary syndromes of hyperalgesia[156] or insensitivity to pain.[157] A monoclonal antibody has been described which is 1000 times more potent at blocking sodium currents through Nav1.7 than those of other isoforms.[158] Importantly, animal models of visceral pain suggest a substantial role of Nav1.9 in these syndromes.[25]

TARGETING OF NOCICEPTIVE FIBERS

High hopes had been raised by reports of sensory-selective blockade of peripheral nerves when a quaternary derivative of lidocaine was targeted into nociceptors using activation of TRPV-1 channels by lidocaine or capsaicin. TRPV channels are preferentially located in small sensory fibers.[159] After several promising studies, concerns over neurotoxicity[151] prevented this combination from entering clinical practice. Yet, the concept of targeting specific variants of local anesthetic drugs into specific fibers has been confirmed, and if a combination of drugs is found which can provide these effects with decreased neurotoxicity, the strategy as such may hold promise. Whether any quaternary derivatives of local anesthetics have less neurotoxicity than their parent compounds remains as of yet unanswered.

To summarize, several avenues of research may lead to new local anesthetics or new modes of application, but only liposomal bupivacaine has been introduced into clinical practice. Potentially, these new strategies may move us closer to the holy grail of regional anesthesia, where patients benefit from a tailored surgical block followed by prolonged periods of reliable sensory (or even nociceptive) block without impairment in motor function.

Biologic Mechanisms of Local Anesthetic Failure: Inflammation, Hyperalgesia, Tachyphylaxis, and Genetic Variants

Failure of local anesthesia is commonly ascribed to technical failure of delivery, insufficient volume or concentration of drug, or erroneous clinical decisions in selection of techniques. However, there are a number of clinical situations in which biologic processes contribute to failed local anesthesia, even with proper technique and drug selection.

For example, in patients going to the dentist with infections such as a tooth abscess or severe pulpitis, failure rates of standard doses of local anesthetic have been reported to be as high as 70%. Local anesthetic failure at a site of inflammation appears to reflect a combination of pharmacokinetic factors and pharmacodynamic factors. Pharmacokinetic factors include (1) increased local blood flow leading to accelerated removal of drug from perineural injection compartments; (2) local tissue acidosis leading to a greater proportion of the drug in the hydrochloride form, which diffuses more poorly across biologic membranes; and (3) local tissue edema, which increases diffusion distances for drug into nerves. Pharmacodynamic factors include the effects of inflammation on both peripheral sensitization of nerves and central sensitization.[120] It is noteworthy that in the setting of an infected mandibular tooth, inferior alveolar nerve block (performed proximally at a site presumably remote from the infected area) also has an unexpectedly high failure rate. Increasing the concentration of local anesthetic can still result in satisfactory, albeit shorter, blockade. In clinical practice, these patients require a higher local anesthetic dose to achieve sufficient analgesia. Inflamed tissue is more difficult, but not impossible, to anesthetize.

Apparent reductions in the effectiveness of local anesthetic infusions over time may be due to a number of causes unrelated to tolerance per se, including dislodgement of catheters and changes in the dermatomal origin or intensity of nociceptive input. In obstetric patients receiving epidural bolus injections, recurrence of pain before the next injection resulted in a reduction in the intensity and duration of blockade, whereas repeat injection before the return of pain prevented this rapidly occurring form of tolerance, or tachyphylaxis.[160] In postoperative patients, co-administration of systemic opioids prevented regression of segmental block in patients receiving thoracic epidural bupivacaine infusions.[161] Studies in rats suggest that both pharmacokinetic and pharmacodynamic mechanisms are involved. In a rat model, tachyphylaxis was linked to the development of hyperalgesia,[162] and drugs that inhibit hyperalgesia, including *N*-methyl-D-aspartate receptor antagonists and nitric oxide synthase inhibitors,[163] also prevented tachyphylaxis. Conversely, repeated sciatic injections of lidocaine resulted in reduced intraneural lidocaine content along with reduced duration of block.[164] The exact mechanism, however, has not been determined, and the clinical relevance with continuous use of long-acting local anesthetics is unclear.

Occasionally patients report that "local anesthetics don't work for me." Although this claim may reflect previous technical failures or a variety of other processes and patient- or procedure-specific factors, it is possible that in some cases these failures may involve genetic or acquired variation in local anesthetic responsiveness. Several mutations in the transmembrane segment IIIS6 of the rat brain α-subunit have been shown to decrease the affinity between sodium channels and local anesthetics and anticonvulsants[165] and similar investigations have also been carried out in sodium channel subtypes Nav1.7[166] or Nav1.5.[167] Of note, different mutations at specific points in the local anesthetic binding site led to differential response of these channels to sodium channel blockers, suggesting that the binding of local anesthetics to the "receptor" is a more dynamic, fluid, and structure-dependent process than commonly assumed. This is supported by a clinical study which showed that some percent of persons reporting inefficient regional anesthesia really did demonstrate partial resistance when tested in standardized manner, and some patients had selective resistance against specific local anesthetics.[168] While Clendenen and colleagues published the genetic workup of a family with inherited local anesthetic resistance,[167] there are preliminary hints that local anesthetic resistance may also be acquired. Interesting case reports suggest that repeated exposure to scorpion bites can elicit acquired resistance to local anesthetics.[169] Elements of scorpion toxin are known to interact with sodium channels, albeit at other sites (Site 3 and 4) than local anesthetics (which bind to Site 9),[170] and therefore the sustained modulation of sodium channel function by toxins is yet another fascinating potential facet of sodium channel and local anesthetic pharmacology.

Conclusions

Local anesthetics have been a central pillar in perioperative management of patients for more than a century, and continued research will assure that we know as much as possible about these drugs, and how we can use them as optimally as possible for the benefit of the patients whose care has been entrusted to us.

Acknowledgment

The editors, publisher, Dr. Charles B. Berde, and Dr. Philipp Lirk would like to thank Dr. Gary Strichartz for his contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

30 Risk of Anesthesia

RACHEL A. HADLER, MARK D. NEUMAN, and LEE A. FLEISHER

KEY POINTS

- Perioperative risk is multifactorial and may occur as a result of anesthesia-, surgery-, and/or patient-specific factors.
- Anesthesia-related (and surgery-related) risk is typically defined as morbidity and mortality occurring within 30 days of surgery, although events that occur at later points may still be related to anesthesia and/or surgery.
- The overall risk of anesthesia relates to both specific, organ-based complications and the rapidity with which they are managed (i.e., rescued).
- In the literature on anesthesia-related risk, the rates of morbidity and mortality reported across studies show a substantial variability in part attributable to the wide variety of definitions used in these studies.
- Historical studies of anesthesia-related risk identified anesthesia-related respiratory depression as the major cause of death and coma totally attributable to anesthesia. This finding prompted the creation of postanesthesia care units (PACUs).
- Research into anesthesia-related cardiac arrest has found it to be attributable to medication administration, airway management, and technical problems of central venous access.
- Multivariate modeling can be used to determine specific factors associated with an increased likelihood of adverse postoperative events, and it has been used to define a range of clinical risk indices to predict postoperative outcomes.
- Surveys of maternal mortality suggest that although the absolute rate of complications attributable to anesthesia has not decreased over time, the increased use of regional anesthesia may have led to improvements in outcome.
- Medication-related and cardiovascular events were the most common causes of cardiac arrest in the Pediatric Perioperative Cardiac Arrest (POCA) Registry.
- Growth in the number and variety of surgical procedures performed in hospital outpatient departments, ambulatory surgery centers, and physician offices creates novel challenges for assessing and managing perioperative risk.
- Initiatives established over time by the Anesthesia Patient Safety Foundation, the American Society of Anesthesiologists (ASA), and others have sought to decrease the potential risks of anesthesia through systems-level improvements, standardization of care processes, human-factors engineering, and simulation-based training.
- Emerging evidence suggests that the choice of anesthetic drugs, ventilator strategies, or technique may impact patient outcomes.

Introduction

Since the beginning of its modern history, the administration of anesthesia has been recognized as a hazardous enterprise,[1] with distinct risks to the patient and occupational risks to anesthesia providers. From the perspective of public health, understanding both the nature and the magnitude of these risks is important on multiple levels. For individual patients, receiving accurate information on the probability of specific perioperative complications is a prerequisite for informed decision making related to anesthesia and surgery. More broadly, understanding the extent to which rates of perioperative morbidity and mortality vary across patients, physicians, and hospitals provides an important opportunity for assessing and improving quality in healthcare.

Efforts to determine the risks of anesthesia are complicated by many potential perspectives from which such risks can be defined. The use of alternate periods of observation for morbidity and mortality—the intraoperative period alone, the first 48 hours after surgery, the duration of the hospital stay, or the first 30 days or longer after surgery—complicates simple conclusions about the risks faced by any individual patient undergoing anesthesia and surgery and at what point after surgery the likelihood of further adverse events has returned to baseline (Table 30.1). For example,

TABLE 30.1 Time Perspective of Anesthetic Morbidity and Mortality Studies

Study	Study Year	Time Perspective
Beecher and Todd	1954	All deaths on the surgical services
Dornette and Orth	1956	Deaths in the surgical unit or after failure to regain consciousness
Clifton and Hotten	1963	Any death under or attributable to anesthesia or without return of consciousness after anesthesia

Modified from Derrington MC, Smith G. A review of studies of anaesthetic risk, morbidity, and mortality. *Br J Anaesth*. 1987;59(7):815–833.

patients undergoing ambulatory surgery have the lowest risk of death the day of surgery as opposed to 1 month later.[2] At the opposite end of the spectrum, asymptomatic release of cardiac enzymes in the perioperative period can have implications for months to years.[3-5] Divergent conclusions would also be expected from studies that consider adverse events that are solely attributable to the administration of anesthesia versus those that examine the overall rates of morbidity and mortality after surgery, which anesthesia care may modify. Studies exclusively focusing on the intraoperative period have characterized contemporary anesthesia care as a patient safety "success story" as a result of the low rates of death directly attributable to anesthesia care. As a result, anesthesia has been hailed by the National Academy of Medicine as "an area in which very impressive improvements have been made" in terms of patient safety.[6]

Nonetheless, a broader perspective on perioperative outcomes presents a more complicated story. For example, in the case of a patient with established coronary artery disease who sustains a myocardial infarction after experiencing tachycardia during high-risk surgery, the cause of the patient's adverse outcome could arguably be attributed to both the patient's underlying coronary artery disease and to the absence of intraoperative heart rate control. In this situation, the decision to view the perioperative infarction primarily as a consequence of patient disease or as an event that could be prevented by anesthesia care carries vastly different implications for efforts to define and reduce the risks of anesthesia.

Finally, the diverse array of outcomes considered as hazards of anesthesia complicate the interpretation of the literature on the risks of anesthesia. Traditionally, investigators have focused on issues of death and major morbidity such as myocardial infarction, pneumonia, and renal failure. More recently, however, this view has been broadened to include economic outcomes, as well as patient-centered outcomes such as functional independence, quality of life, and satisfaction (Table 30.2). For example, unanticipated rehospitalization after ambulatory surgery or a delay in discharge as a result of postoperative nausea and vomiting are both potentially important from the perspectives of the patient's quality of life, as well as economics.

TABLE 30.2 Examples of Common Outcome Measures

Outcome	Example
Mortality Failure-to-rescue	Mortality after a postoperative complication
Morbidity Major	Myocardial infarction Pneumonia Pulmonary embolism Renal failure or insufficiency Postoperative cognitive dysfunction
Minor	Nausea Vomiting Readmission
Patient satisfaction Quality of life	

In this chapter, current theories regarding the underlying causes of adverse events in the perioperative period are reviewed, and the historical and contemporary literature regarding the nature and magnitude of risk related to both intraoperative anesthesia care and perioperative care are examined. Next, historical and recent efforts to characterize the patient-, provider-, and facility-level determinants of anesthetic and perioperative risk are reviewed through statistical risk indices, and clinically based approaches to patient classification, and available literature on the determinants of risk unique to the obstetric, pediatric, and geriatric populations are discussed. Finally, future directions in research and clinical care related to anesthetic risk are discussed, with a focus on the health policy implications of changing knowledge regarding the hazards of anesthesia.

Framework of Perioperative Risk

Perioperative risk is multifactorial and depends on the interaction of anesthesia-, patient-, and surgery-specific factors (Fig. 30.1). With respect to anesthesia, the selection and effects of medications, including volatile and intravenous anesthetic drugs, and the skills of the practitioner are important. Similarly, the surgeon's skills and the surgical procedure itself also affect perioperative risk. Further, practitioners may influence outcomes at multiple points in the postoperative course. Although the incidence of specific local or organ-based complications, such as perioperative myocardial infarction or central line–related bloodstream infection, may be modified by anesthetic or surgical care, variations in the adequacy of care delivered to patients who have already experienced a complication (i.e., failure to rescue) may largely explain hospital-to-hospital differences in surgical outcomes.[7-9] Notably, although past investigators have pointed to volume-outcome relationships as potentially mitigating these hospital-to-hospital outcome

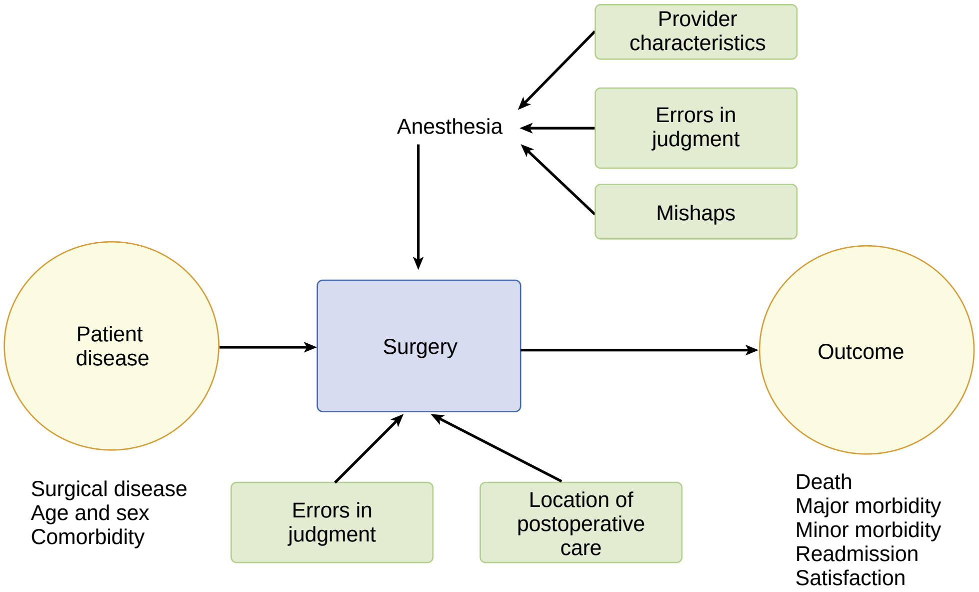

Fig. 30.1 Representation of the influences of various components on poor perioperative outcomes. Surgical, anesthetic, and patient characteristics all contribute to outcome. Anesthesia-related contributions can include issues of judgment and mishaps, as well as characteristics of the provider. The surgical procedure itself affects outcome, as does the location of intraoperative and postoperative care.

differences,[10,11] more recent data have suggested that local quality-improvement efforts, rather than large-scale efforts, at regionalization of care for elective surgeries hold the greatest potential to yield meaningful improvements in operative outcomes.[12]

The potential for anesthetic care to influence the overall hazard of surgery at multiple time points highlights both the complexity of measuring the risks of anesthesia and surgery, and the range of potential opportunities that may exist to reduce such risks. Given these challenges and opportunities, the goal of the next section is to summarize the current state of knowledge in this area, including the relative strengths and weaknesses of randomized and nonrandomized (i.e., observational) study designs used in efforts to understand patterns of outcomes after surgery and anesthesia.

Issues Related to Study Design

TYPES OF STUDIES

To interpret the literature related to anesthetic and perioperative risk, the strengths and limitations of various study designs must be understood. *Prospective cohort studies* involve the identification of a group of subjects who are monitored over time for the occurrence of an outcome of interest. The goal is to identify patients in whom the outcome develops. For studies of perioperative mortality, individual cases can be reviewed to determine the cause of mortality. Alternatively, data on all patients in the cohort study can be obtained, and discrete factors associated with the development of morbidity or mortality can be determined, often using multivariate regression techniques. An example of a prospective cohort study to identify factors associated with perioperative cardiac morbidity and mortality is that of Goldman and colleagues,[13] which led to development of the Cardiac Risk Index.

Although prospective cohort studies have important value in identifying risk factors for perioperative outcomes, they also have significant limitations. The range of patients enrolled in the cohort study, both in terms of baseline characteristics and the care they receive, may impact the generalizability of the study findings. Additional biases may be introduced by loss of patients to follow-up. Failure to anticipate the potential impact of some variables and collect data on them may limit the insights gained from a cohort study. Similarly, the inability to collect data on all potential confounders of the relationship between a putative risk factor and a given outcome limits the extent to which cohort studies can support causal inferences.

Randomized clinical trials offer stronger evidence of causality than do observational cohort studies. In a randomized trial, subjects are assigned by random allocation to one of two or more treatments (potentially including a placebo) and are observed for the development of a particular outcome. In the context of perioperative risk, randomized trials may be used to determine the efficacy of an intervention or anesthetic regimen intended to improve postoperative outcomes. For example, hypothermia in the perioperative period has been associated with an increased incidence of perioperative ischemia, a surrogate marker for morbidity.[14] In a randomized clinical trial, the use of forced-air warming to maintain normothermia was associated with a significantly less frequent incidence of perioperative morbid cardiac events.[15] Randomized clinical trials often build on hypotheses generated in cohort studies regarding the determinants of outcomes by testing interventions directed at a specific risk factor associated with adverse outcomes.

Randomized clinical trials derive their strength from their high degree of internal validity; the randomization scheme and the use of placebo (or accepted alternative treatments) provide strong evidence that the results are related to the intervention. Importantly, these trials may have a lower degree of external validity because the intervention tested in a particular trial may not work as well or in the same manner as when it is diffused into a more heterogeneous population. Further, as a result of sample size limitations, clinical trials may often be unable to detect subtle differences in outcomes among study groups or differences in rare events.

Retrospective studies involve the identification of patients who have sustained an outcome and definition of risk factors associated with the outcome. An example of a retrospective design is a case-control study. *Case-control studies* identify patients with the outcome of interest. Frequently, these patients are included as part of a prospective cohort study. The prevalence of a risk factor in patients with the outcome (i.e., cases) is compared with the prevalence of the risk factor in matched control participants to maximize the efficiency and power of the results. The ratio of cases to control participants can be varied to yield greater power with an increasing number of controls. An alternative retrospective design involves the systematic review of identifiable adverse events for patterns of error. For example, Cheney and colleagues[16] developed the American Society of Anesthesiologists' Closed Claims Project (ASA-CCP) to assess the risks associated with anesthesia care. By obtaining the records of major events that led to legal litigation, they were able to identify factors that contributed to bad outcomes. With this methodology, selected morbidities that led to litigation can be identified. The limitation of this methodology is that the actual rates of complications in the overall population are not known; only the number of closed legal claims is identified. Cases that do not result in litigation are not included in the database.

PROBLEMS INHERENT IN STUDYING ANESTHESIA-RELATED RISK

Studying anesthesia-related risk involves a range of methodologic challenges. On the most basic level, multiple definitions exist for key outcomes, such as perioperative mortality. In particular, the timeframe in which a death can be attributed to the surgery or the delivery of anesthesia or both varies. Notably, many events related to surgery may occur after discharge when monitoring of outcomes becomes more challenging. For this reason, the National Surgical Quality Improvement Program (NSQIP), a large, prospectively collected U.S. registry of surgical care and outcomes, requires 30-day follow-up on all patients to allow for consistent assessments of outcomes for all patients.

A second major challenge in any study of postoperative outcomes is the low observed rate of many key outcomes in the population of interest. Although some recent writers have called into question the safety of contemporary anesthesia care,[17] anesthesia-related death remains relatively uncommon in absolute terms. For example, the rate of anesthesia-related mortality described in the Confidential Enquiry into Perioperative Deaths (CEPOD) of 1987 was 1 in 185,000 patients as opposed to the 1 in 2680 cases reported by Beecher and Todd approximately 30 years earlier.[18,19] As a result, efforts to identify the range of factors that now contribute to anesthetic mortality are likely to require large patient cohort studies available either from administrative sources or collected over several years from multiple institutions. Several attempts have been made to establish large epidemiologic databases to address this challenge. One example of such an approach has been the work of Dennis Mangano and the Multicenter Study of Perioperative Ischemia Research Group with regard to cardiac surgery. This group used its database to evaluate issues such as the rate and importance of atrial fibrillation after cardiac surgery and the association of perioperative use of aspirin with cardiac surgical outcomes.[20,21] Other approaches include the development of cardiac surgery databases by the Society of Thoracic Surgeons, the U.S. Veterans Administration NSQIP, and the Northern New England Cardiovascular Disease Study Group.[22-25] These databases are used to define risk factors for poor outcome, to compare local with national complication rates, and as educational tools. In the United States, the Multicenter Perioperative Outcomes Group has undertaken such an enterprise by pooling electronically collected intraoperative and postoperative data.[26] Although these databases may provide extremely important information to improve care, the ability to generalize results to centers that do not have sufficient infrastructure to participate in such projects (e.g., smaller hospitals) is unknown.

Variations in care and outcomes across institutions may further complicate efforts to develop meaningful estimates of perioperative risk for use in clinical decision making by individual patients. Beyond the impact of patient illness, type of surgery, or anesthetic approach, hospital-level differences in postoperative care may have a profound impact on outcome. For example, the incidence of pulmonary embolism may be related to nursing care and the frequency of patient ambulation after surgery[27]; similarly, the presence of an intensivist who makes daily rounds and higher nurse staffing ratios may also affect outcome.[28]

Finally, issues of risk adjustment complicate efforts to determine changes in anesthesia risk over time. Common endpoints, such as mortality, are influenced by patient factors as well as by anesthesia and surgical care; as such, temporal trends in patient acuity may influence the apparent adverse outcomes associated with anesthesia and surgery in a given period. With appropriate risk adjustment, changes in mortality rates over short periods may provide some indication of changes in the quality of anesthesia or surgical care. When viewed over longer periods, however, it may be more difficult to reach firm conclusions regarding temporal changes in the safety of anesthesia or surgery based on differences in mortality rates over time. For example, if improvements in anesthetic technology have allowed for older and sicker patients to undergo surgery, then the safety of anesthesia may have improved without any apparent change in mortality rates because a sicker patient population is now offered surgery that, in the past, would have been avoided. Similarly, the rapid adoption of new but relatively high-risk procedures complicates simple comparisons of anesthesia-related complications over time.

STUDIES OF ANESTHESIA-RELATED MORTALITY

Efforts to understand the specific risks imposed by anesthesia care, above and beyond the surgical procedure itself, have represented an important dimension of research in anesthesia since the early 20th century. Although more recent trends in anesthesia research have emphasized a

broad view of perioperative outcomes not strictly limited to events primarily caused by anesthesia care,[30] the history of efforts to determine the safety of anesthesia management represents an important chapter in the development of modern perioperative medicine. This history also serves as important background for understanding current research and practice.

Research performed before 1980 demonstrated wide variation in reported rates of anesthesia-related mortality (Table 30.3). Beecher and Todd's 1954 report of anesthesia-related deaths at 10 institutions represents the earliest published major analysis of anesthesia outcomes.[18] Their study included 599,548 anesthesia procedures and found a rate of all-cause mortality of 1 per 75 cases (1.3%). In 1 out of every 2680 procedures, anesthesia represented the primary cause of mortality, and it was a primary or contributory cause of mortality in 1 of 1560 procedures. The work of Dornette and Orth[31] investigating perioperative deaths over a 12-year period at their institution corroborated these findings: they reported a mortality rate attributable to anesthesia in 1 in 2427 cases, and totally or partially attributable to anesthesia in 1 in 1343 cases. In contrast, Dripps and colleagues found the anesthesia-attributable mortality rate to be 1 in 852 in a similar single-institution longitudinal study.[32] These differences may be partially explained by Dripps' observation of 30-day, rather than intraoperative or 48-hour mortality, or differences in patient severity across studies.

Multiple additional studies on anesthetic mortality appeared between 1960 and 1980.[33] In the United States, these included the Baltimore Anesthesia Study Committee,[34] which reviewed 1024 deaths occurring on the day of or the day after a surgical procedure, and several single-institution studies.[35,36] Overall, the rate of anesthesia-related mortality in these studies varied widely, ranging from 1 in 1232 cases in a study by Schapira et al[35] to 1 in 7692 cases in the Baltimore Anesthesia Study Committee report. Results from the international community during that period were similarly heterogeneous in methodology and findings.[37-40]

TABLE 30.4 Incidence of Complications Partially or Totally Related to Anesthesia

Complications	Partially Related	Totally Related	Total*
All complications	1:1887	1:1215	1:739
Death	1:3810	1:13,207	1:1957
Death and coma	1:3415	1:7924	1:2387

*Total number of anesthetics: 198,103. From Tiret L, Desmonts JM, Hatton F, Vourc'h G. Complications associated with anaesthesia—a prospective survey in France. *Can Anaesth Soc J*. 1986;33:336–344.

Studies of anesthetic risk published before 1980 varied widely in the definitions used for anesthesia-related mortality and in the mortality rates they reported; however, they suggested that death related solely to anesthesia was a relatively uncommon event. Moreover, an overall trend toward lower rates of anesthesia-related mortality across studies over time suggested potential improvements in anesthesia safety.

Studies since 1980 have generally been performed on a regional or national basis with a particular emphasis on documenting changes over time in anesthesia-related mortality. For example, Holland[41] reported deaths occurring within 24 hours after anesthesia in New South Wales, Australia. The incidence of anesthesia-attributable deaths decreased from 1 in 5500 procedures performed in 1960 to 1 in 26,000 in 1984. Based on these estimates, the investigators asserted that for all patients receiving surgery, it was more than five times safer to undergo anesthesia in 1984 than it was in 1960.[42]

Under the direction of the French Ministry of Health, Tiret and colleagues[43] carried out a prospective survey of complications associated with anesthesia in France between 1978 and 1982 from a representative sample of 198,103 anesthesia procedures from hospitals throughout the country. Death was solely related to anesthesia in 1 in 13,207 procedures and partially related in 1 in 3810 (Table 30.4). The French survey confirmed previous findings that major complications occur more frequently in older patients, those undergoing emergency surgical procedures, and those with more extensive comorbid conditions as measured by ASA physical status classification. More notably, the investigators found that postanesthesia respiratory depression was the leading principal cause among cases of death and coma that were solely attributable to anesthesia. Moreover, almost all the patients who had had respiratory depression leading to a major complication had received narcotics, as well as neuromuscular blocking drugs, but they had not received anticholinesterase medications for reversal of the agents.

Despite these observations, the low rates of anesthesia-attributable mortality documented in the French study offered compelling evidence of improvements in anesthesia safety. Such findings were reinforced by other, concurrent work in Finland[44] and in the United Kingdom,[45] resulting in the development of the United Kingdom CEPOD, which

assessed almost 1 million anesthetics during a 1-year period in 1987 in three large regions of the United Kingdom.

Beyond confirming earlier work, CEPOD's findings suggested that anesthesia care was far safer than had been found in prior studies. Examining deaths within 30 days of surgery, CEPOD investigators observed 4034 deaths in an estimated 485,850 surgeries for a crude mortality rate of 0.7% to 0.8%. Anesthesia was considered the sole cause of death in only three individuals, for a rate of 1 in 185,000 cases, and anesthesia was contributory in 410 deaths, for a rate of 7 in 10,000 cases (Table 30.5).[19] The five most common causes of death in the CEPOD cohort study are shown in Table 30.6. Notably, of the 410 perioperative deaths, gastric aspiration was identified in 9 cases and cardiac arrest in 18 cases. Ultimately, CEPOD researchers concluded that avoidable factors were present in approximately 20% of the perioperative deaths. Contributing factors for anesthesiologists and surgeons tended to be failure to act appropriately with existing knowledge (rather than a lack of knowledge), equipment malfunction, fatigue, and inadequate supervision of trainees, particularly in off-hours shifts (Table 30.7).

Large national studies performed since the 1987 CEPOD report vary in the extent to which their findings agree with those of the CEPOD investigators. In a prospective study of 7306 anesthesia procedures in Denmark, Pedersen and colleagues[46] found complications attributable to anesthesia in 43 patients (1 in 170) and 3 deaths (1 in 2500), an incidence far higher than that documented by the CEPOD investigators. Complications in the 43 patients, in order of incidence, included cardiovascular collapse in 16 (37%), severe postoperative headache after regional anesthesia in 9 (21%), and awareness under anesthesia in 8 (19%).

In the United States, Li and colleagues[47] conducted a population-level study to estimate epidemiologic patterns of anesthesia-related deaths, using International Classification of Diseases (ICD) codes listed in the United States multiple-cause-of-death data files for the years 1999 through 2005. Although the interpretation of Li's study is complicated by questions surrounding the sensitivity of ICD codes for anesthesia-related mortality,[48] their findings are in accord with those of the CEPOD report in presenting anesthesia-related mortality to be an extremely rare cause of death at the population level. The authors found anesthesia to be the underlying cause of death in 34 patients each year in the United States and a contributing factor in another 281 deaths annually, resulting in a 97% decrease in anesthesia-related death rates since the 1940s.

Recent European studies have taken a broader focus beyond anesthesia-related events to examine perioperative outcomes more generally, particularly among high-risk patients who Lagasse and others previously observed to account for the majority of postoperative deaths.[17] In a 2011 report, NCEPOD investigators prospectively collected data on all patients undergoing inpatient surgery, excluding obstetric, cardiac, transplant, or neurosurgery cases, in United Kingdom National Health Service facilities over a 1-week period.[49] In addition to prospectively collected patient-level data on clinical care and outcomes, the authors conducted a detailed institution-level survey of resources and practices. Although the authors observed an overall 30-day mortality rate of 1.6%, a subset of high-risk patients—approximately 20% of the full cohort—experienced a disproportionate share of adverse outcomes, accounting for 79% of all perioperative deaths. Notably, the authors identified important gaps in the perioperative management of these patients. A minority of the high-risk patients were monitored using an arterial line, a central line, or cardiac output monitoring; still more concerning was their observation that 48% of all high-risk patients who died were never admitted to a critical care unit for postoperative management. Similar findings were obtained in another study of surgical outcomes conducted across 28 European countries between April 4 and April 11, 2011.[50] Such patterns, which the authors describe as a "systematic failure in the process of allocation of critical care resources" in Europe, highlight the potential importance of "rescue"—the prevention of mortality among patients who experience postoperative complications—in determining the outcomes of surgical care. Further, to the extent that critical care use among patients who die after surgery is higher in the United States than in the United Kingdom,[51] such differences may offer insight into potential reasons for earlier observations of lower risk-adjusted postoperative mortality among American versus British surgical patients.[52]

In the United States, Whitlock and colleagues[52a] retrospectively analyzed 2,948,842 cases logged in the National Anesthesia Clinical Outcomes Registry between 2010 and 2014. They documented a mortality rate of 33 per 100,000. Increasing ASA physical status, emergency case status, time of day, and age less than 1 year or greater than 65 years were independently associated with perioperative mortality. After adjustment for confounding factors, mortality remained greater for cases started after 6 PM, suggesting that certain factors influencing perioperative mortality might be modifiable. The most common concurrent outcomes in patients who died within 48 hours of anesthesia were hemodynamic instability (35.0%) and respiratory complications (8.1%). Notably, due to data limitations, the authors did not comment on the number of deaths that were anesthesia associated.

In summary, research on anesthesia-related mortality offers a complex and still incomplete picture regarding the risks of anesthesia. Taken from the perspective of the 1987 CEPOD report or the findings of Li and colleagues, modern operative anesthesia could be characterized as an exceedingly safe enterprise with bad outcomes occurring as truly rare events; however, other studies have disputed these findings. More recent work has sought to go beyond efforts to quantify the contribution of anesthesia per se to overall operative risk to explore how anesthesia providers might be able to improve outcomes among high-risk patients—in essence asking not "how safe is anesthesia?" but instead "how can anesthesia providers help make surgery safer?" Ultimately, these studies' differing messages emphasize not only the dynamic nature of anesthesia risk over time, but also highlight important changes in how anesthetic risk has been defined across different periods and how alternate approaches to evaluating, describing, and mitigating such risk may be more or less relevant at a given moment in time.

ANALYSIS OF INTRAOPERATIVE CARDIAC ARREST

In an alternative approach to evaluating perioperative mortality specific to anesthesia, several studies have evaluated intraoperative fatal and nonfatal cardiac arrest. In contrast to efforts to estimate the mortality attributable to anesthesia per se, studies of intraoperative cardiac arrest may offer a broader picture of the potential hazards of anesthesia by examining an adverse outcome that is far more common than mortality yet remains highly consequential for long-term outcomes.

These studies offer a range of perspectives on the incidence of intraoperative cardiac arrest and the causes of such events. For example, Keenan and Boyan[53] studied the incidence and causes of cardiac arrest related to anesthesia at the Medical College of Virginia between 1969 and 1983. A total of 27 cardiac arrests occurred during 163,240 procedures, for an incidence of 1.7 per 10,000 cases. Fourteen patients died, for an incidence of 0.9 per 10,000 cases. Pediatric patients had a threefold higher risk of cardiac arrest than did adults, and emergency cases had a sixfold greater risk. Importantly, specific errors in anesthesia management could be identified in 75% of the cases; most common among these were inadequate ventilation and overdose of an inhaled anesthetic. Notably, the investigators identified progressive bradycardia preceding all but one arrest, suggesting that early identification and treatment may prevent complications.

Similar findings were reported by Olsson and Hallen,[54] who studied the incidence of intraoperative cardiac arrest at the Karolinska Hospital in Stockholm, Sweden, from 1967 to 1984. A total of 170 arrests occurred in 250,543 anesthesia procedures performed. Sixty patients died, for a mortality rate of 2.4 per 10,000 procedures. After eliminating cases of inevitable death (e.g., rupture of a cerebral aneurysm, trauma), the rate of mortality caused by anesthesia was 0.3 per 10,000 procedures. The most common causes of anesthesia-related cardiac arrest were inadequate ventilation (27 patients), asystole after succinylcholine (23 patients), and postinduction hypotension (14 patients). The incidence of cardiac arrest was highest in the patients with significant comorbid disease, as assessed by the ASA physical status classification. Notable is the finding that the incidence of cardiac arrest decreased over the study period. These findings were reproduced in other studies, including that of Biboulet and colleagues[55] and Newland and associates.[56]

TABLE 30.8 Selected Cardiac Arrest Series When the Denominator Is Greater Than 40,000 Anesthetics

Sprung and colleagues[57] demonstrated similar findings with regard to incidence and outcome of cardiac arrest during 72,529 procedures between 1989 and 1999 in a teaching hospital in the United States. They also found that the frequency of arrest in patients receiving general anesthesia decreased over time (7.8 per 10,000 during 1990-1992; 3.2 per 10,000 during 1998-2000). The frequency of arrest during regional anesthesia (1.5 per 10,000) and monitored anesthesia care (MAC) (0.7 per 10,000) remained the same during the study period (Fig. 30.2). More recently, Ellis and group[57a] used an institutional quality improvement database to identify all instances of cardiac arrest occurring within a 24-hour perioperative period between 1999 and 2009. They identified 161 arrests in 217,365 anesthetics, 14 of which were found to be anesthesia-attributable (0.6 per 10,000 anesthetics) and 23 that were anesthesia-contributory (1.1 per 10,000). Of anesthesia-attributable events, the majority (64%) were caused by airway complications during induction or emergence. The mortality associated with these events was 29%.

Kawashima and colleagues identified even lower rates of cardiac arrest attributable to anesthesia in a survey-based study conducted in Japan from 1994 through 1998.[58] The average yearly incidence of cardiac arrest during surgery that was totally attributable to anesthesia was 1 per 10,000 cases (95% CI, 0.88-1.12). The average mortality per year in the surgical unit or within seven postoperative days that was totally attributable to anesthesia was 0.21 (0.15-0.27) per 10,000 cases. The two principal causes of cardiac arrest solely attributable to anesthesia were drug overdose or selection error (15.3%) and serious arrhythmia (13.9%). Preventable human errors caused 53.2% of cardiac arrests and 22.2% of deaths in the surgical unit that were totally attributable to anesthesia. The outcomes of cardiac arrests totally attributable to anesthesia are shown in Table 30.9.

Kheterpal and colleagues at the University of Michigan examined predictors of cardiac adverse events—including cardiac arrest, myocardial infarction, and clinically significant arrhythmia—among 7700 patients undergoing noncardiac surgery. Eighty-three patients (1.1%) experienced an adverse event. The authors identified nine independent predictors of an adverse event: (1) age 68 years or older, (2) body mass index of 30 or greater, (3) emergency surgery, (4) previous coronary intervention or cardiac surgery, (5) active congestive heart failure, (6) cerebrovascular disease, (7) hypertension, (8) operative time of 3.8 hours or longer, and (9) the intraoperative administration of one or more units of packed red blood cells.[60]

In summary, perioperative cardiac arrest is a relatively rare event whose incidence may be decreasing over time. Further, research in this area has highlighted the role of both patient factors and intraoperative care as contributing to the risk of intraoperative and postoperative cardiac arrest and emphasized the management of ventilation and the selection and dosing of anesthetic medications as key areas of focus for the prevention of such events.

PERIOPERATIVE MORTALITY AND MORBIDITY IN OUTPATIENT SURGERY

In the United States, an estimated 60% of all surgical procedures are performed on an outpatient basis, and this percentage is increasing annually. The type and extent of surgical procedures performed in an outpatient setting are constantly changing, and more complicated procedures associated with greater perioperative risk are increasingly being performed on an outpatient basis.

Notably, early research on the safety of two ambulatory surgical procedures—tonsillectomy and simple mastectomy—presented a negative view of the hazards of surgery in the outpatient setting. One of the first procedures advocated to be performed on an ambulatory basis was tonsillectomy. Although a 1968 case series of 40,000 outpatient tonsillectomies reported no deaths,[61] details on patient selection and length of postoperative monitoring were vague. Based on insurance company and state mandates, performance of tonsillectomy on an outpatient basis became routine.[62] Beginning in the mid-1980s and continuing in the 1990s, a number of articles evaluated outcomes with early discharge after tonsillectomy. For example, Carithers and colleagues[63] in 1987 at Ohio State University reported on 3000 tonsillectomies and argued that early discharge might be hazardous and economically unwarranted. The rate of readmission for active bleeding between 5 and 24 hours after surgery was reported to be between 0.2% and 0.5%.[64-67] More recently, Cote and his co-investigators in the Society for Pediatric Anesthesia[67a] used a survey instrument as well as analysis of the ASA-CCP to investigate adverse events associated with tonsillectomy in children. They identified a total of 111 events occurring between 1999 and 2010. Death was the most common outcome (66%), followed by neurologic injury (11%) and prolonged hospital stay (10%). Events in children at risk for obstructive sleep apnea (OSA) were more frequently attributed to apnea, whereas children not at risk for OSA were more likely to experience adverse events secondary to hemorrhage. Fifty percent of patients with postoperative events had received postoperative opioids, including 61% of those children who experienced apneic events in the next 24 hours. Events occurred in multiple locations (the operating room, postanesthesia care unit [PACU], and after discharge). In spite of the limitations in the largely self-reported data, these findings clearly suggest that tonsillectomy remains a procedure with significant associated risk, even in the ambulatory setting.

Mastectomy represents a second important case study in the development of surgery as an outpatient procedure. An analysis of Medicare claims demonstrated that the rate of outpatient mastectomy increased from a negligible proportion of all mastectomies in 1986 to 10.8% of all mastectomies performed among Medicare beneficiaries in 1995.[68] Within this population, simple mastectomies performed on an outpatient basis had a significantly higher rate of readmission than did those undergoing a 1-day hospital stay, with an adjusted odds ratio of 1.84. Additionally, rates of readmission after 1-day stays were significantly lower for infection (4.1 vs. 1.8 per 1000 cases), nausea and vomiting (1.1 vs. 0 per 1000 cases), and pulmonary embolism or deep venous thrombosis (1.1 vs. 0 per 1000 cases).

More recent research suggests that, for some procedures, mere exposure to anesthesia in the outpatient setting may present an increased risk for complications. In 2013, Cooper and colleagues[68a] reviewed outcomes for a sample of cancer-free Medicare beneficiaries in the Surveillance, Epidemiology, and End Results database undergoing outpatient colonoscopy without polypectomy, and compared outcomes including hospitalization and aspiration pneumonia for those undergoing procedures with or without deep sedation (anesthesia services). The researchers identified 35,128 (21.2%) procedures with anesthesia services in a total of 100,359 patients; overall complications were more common in patients who had received anesthesia (0.22% vs. 0.16%, $P < .001$). Aspiration was also more common in the anesthesia group (0.14% vs. 0.1%, $P = .02$). Multivariate analysis also demonstrated an increased risk of complications associated with use of anesthesia (odds ratio 1.46, 95% CI 1.09-1.94).

In contrast to these procedure-specific studies, the 1993 publication of Warner and colleagues[69] on major morbidity and mortality within 1 month of ambulatory surgery strongly argued for the safety and feasibility of surgery in the outpatient setting. Among the 38,598 patients included in Warner's study, four died. Of these four deaths, two were due to myocardial infarctions occurring more than 1 week after surgery; the other two deaths occurred in automobile accidents (Fig. 30.3). Partially as a result of these findings, the use of ambulatory surgery has dramatically grown between the early 1990s and the present, with a concurrent increase in the number and type of sites for ambulatory surgery. Such sites now include not only freestanding ambulatory surgery centers (ASCs) and physician's offices, but they also include interventional radiology units and other diagnostic and therapeutic sites not affiliated with any other healthcare facility.

In the context of such growth, investigators have sought to examine the relative safety of similar procedures performed across different outpatient settings. Fleisher and co-workers[2] performed a claims analysis of patients undergoing 16 different surgical procedures in a nationally representative (5%) sample of Medicare beneficiaries for the years 1994 through 1999. A total of 564,267 procedures were studied, with 360,780 in an outpatient hospital, 175,288 in an ASC, and 28,199 in a physician's office. On the day of surgery, no deaths occurred in the office, but four deaths occurred in the ASC (2.3 per 100,000) and nine deaths occurred in the outpatient hospital (2.5 per 100,000). The 7-day mortality rate was 35 per 100,000 in the office setting, 25 per 100,000 in the ASC, and 50 per 100,000 in the outpatient hospital. The rate of admission to an inpatient hospital within 7 days was 9.08 per 1000 in the office, 8.41 per 1000 in the ASC,

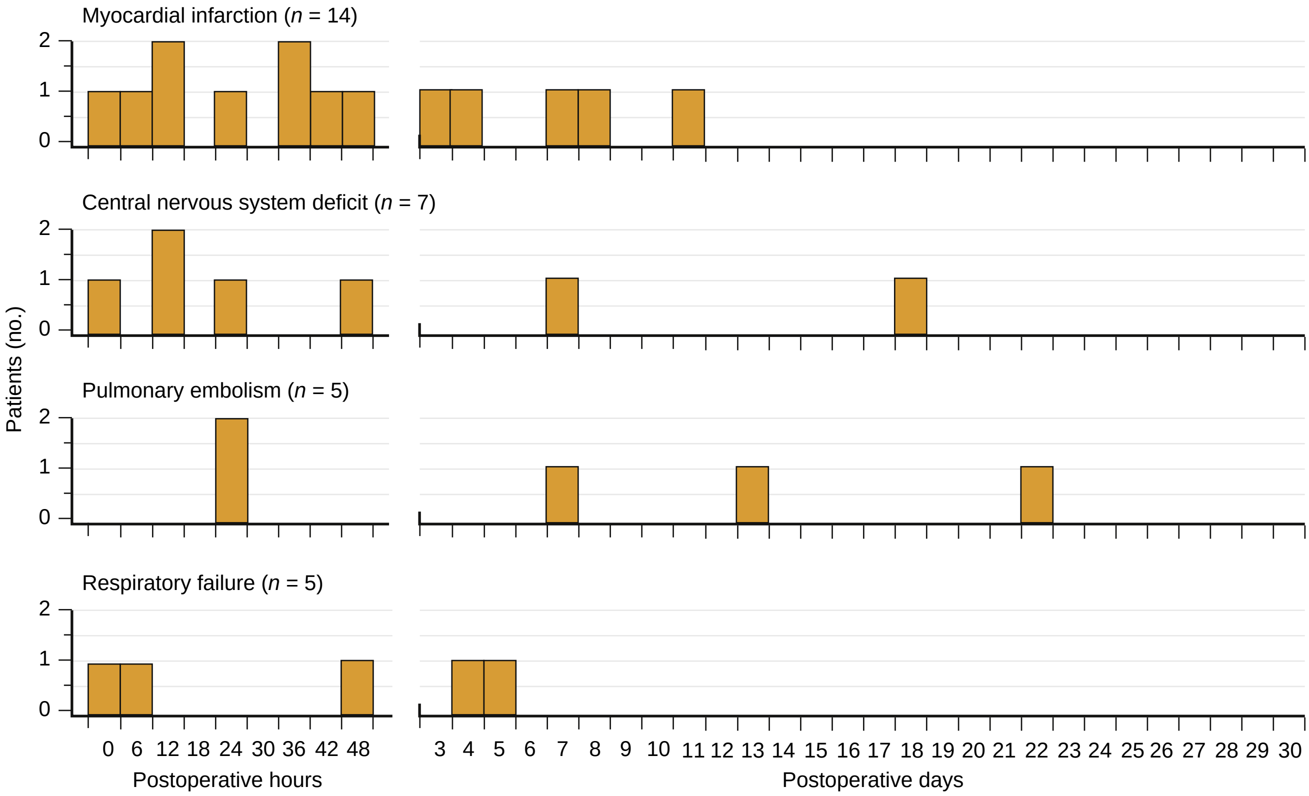

Fig. 30.3 Timing of perioperative events in patients undergoing ambulatory surgery. Many of the events occurring within the first 48 hours are probably related to the stress of surgery. A subset of events occurring after this period may be related to background event rates. The overall rate of morbidity was lower than expected for a similar cohort of age-matched nonsurgical patients. (From Warner MA, Shields SE, Chute CG. Major morbidity and mortality within 1 month of ambulatory surgery and anesthesia. *JAMA.* 1993;270(12):1437–1441.)

and 21 per 1000 in the outpatient hospital. Notably, the inferences of this study are limited by an inability to distinguish fully whether these differences in outcomes are related to the differences in the types of patients selected to have surgery in each setting versus the differences in the care patients received in each setting.

Subsequent work by Chukmaitov and colleagues compared quality outcomes between ASCs and hospital-based outpatient departments in the state of Florida between the years 1997 and 2004.[71] Although their conclusions were limited by differences in the data available for patients treated in each setting, they postulated that the difference in outcomes between the two locations may be related to variations in organizational structure, processes, and strategies.

In contrast to the growing literature on the safety of anesthesia and surgery in ASCs, limited information exists to quantify the incidence of complications in office-based settings. The American Association for Ambulatory Plastic Surgery Facilities mailed a survey to their members to determine the incidence of complications occurring in office facilities.[72] The overall response rate was 57%. The findings showed that 0.47% of patients had at least one complication, including bleeding, hypertension, infection, and hypotension, and 1 in 57,000 patients died. Although low in absolute terms, the observation of a rate of mortality after minor outpatient procedures that is three times the current estimate for anesthesia-related complications is concerning in this context.

Vila and colleagues reviewed all adverse incident reports to the Florida Board of Medicine for procedures dated April 1, 2000, to April 1, 2002.[73] Adverse incidents occurred at a rate of 66 and 5.3 per 100,000 procedures in offices and ASCs, respectively. The death rate per 100,000 procedures performed was 9.2 in offices and 0.78 in ASCs. The relative risk (RR) for injury and death for procedures performed in offices versus ASCs was 12.4 (95% CI, 9.5-16.2) and 11.8 (95% CI, 5.8-24.1), respectively. As a result, the authors concluded that if all office procedures had been performed in ASCs, approximately 43 injuries and 6 deaths per year could have been prevented. However, several other groups have also analyzed the Florida data and have been unable to document the increased risk in the office setting.[74-76]

In summary, although early research on ambulatory surgery placed an emphasis on the undue risks created by premature discharge, more recent analyses confirm that a range of surgeries can be safely performed in properly selected patients. Although some variations in outcomes have been observed across settings (i.e., hospital outpatient department vs. ASC), available literature suggests that, given proper patient selection, outpatient surgeries can be performed with a low rate of adverse events in multiple practice environments. Given the gradual expansion of outpatient surgery over time to include patients with greater burdens of comorbid disease and more extensive procedures, ongoing evaluations will be essential to characterize the dynamic, evolving nature of anesthetic risk in the ambulatory setting.

USE OF ANESTHESIA INFORMATION MANAGEMENT SYSTEMS

Over the past four decades, the use of computerized databases has enhanced the ability to assess perioperative risk and complications.

In one of the earliest computer analyses of postanesthesia deaths, Marx and associates[36] identified 645 individuals who died within 7 days after surgery out of a total cohort of 34,145 consecutive surgical patients. More recently, the growth of electronic anesthesia record systems has allowed for better insights into the causes of anesthesia-related events within the surgical unit, and, when used in combination with other data sources, on postoperative outcomes. An early example of such an analysis was that of Sanborn and colleagues,[77] who used a computer anesthesia record to identify intraoperative incidents. They were able to demonstrate that perioperative deaths occurred more frequently in patients who sustained an intraoperative incident of any type than in those who did not. Reich and colleagues similarly used computerized anesthesia records to evaluate hemodynamic variables and their relationship to risk.[78] They identified pulmonary hypertension, hypotension during cardiopulmonary bypass, and post–cardiopulmonary bypass pulmonary diastolic hypertension as independent predictors associated with mortality, stroke, and perioperative myocardial infarction over and above the effects of other preoperative risk factors.

More recently, data from the University of Michigan anesthesia information management system have been used to identify predictors of perioperative risk, including that of inadequate mask ventilation and of postoperative acute kidney injury. In the former evaluation of 22,660 patients,[79] limited or severely limited mandibular protrusion, abnormal neck anatomy, sleep apnea, snoring, and a body mass index of 30 $\mathrm{kg/m^2}$ or greater were independent predictors of grade 3 or 4 mask ventilation and difficult intubation. Review of 15,102 patients who had a normal preoperative creatinine clearance and underwent noncardiac surgery[80] demonstrated that acute renal failure developed in 121 patients (0.8%), with 14 requiring renal replacement therapy (0.1%). Seven independent preoperative predictors were identified: age, emergency surgery, liver disease, body mass index, high-risk surgery, peripheral vascular occlusive disease, and chronic obstructive pulmonary disease necessitating chronic bronchodilator therapy. Acute renal failure was associated with increased mortality from any cause at 30 days, 60 days, and 1 year.

In an effort to expand upon the insights gained from single-institution studies, two major efforts have since been initiated to pool electronic data on anesthesia care from multiple sites as a means of more effectively comparing outcomes and defining risk factors related to outcomes after anesthesia. The first of these, the Multicenter Perioperative Outcomes Group, was initiated in 2008 under the leadership of investigators at the University of Michigan. This project currently collects electronic anesthesia data from over 50 participating anesthesia departments in two countries. To date, the group has released a series of observational studies, including a report on the risks and outcomes of epidural hematomas after perioperative and obstetric epidural catheterization[26] and a subsequent report evaluating the risk of epidural hematoma after neuraxial anesthesia in thrombocytopenic parturients.[80a] Other projects have evaluated predictors of difficult mask ventilation and intubation via direct laryngoscopy,[80b] as well as the success of a variety of rescue intubation techniques following direct laryngoscopy.[80c] The Multicenter Perioperative Outcomes Group recently established Initiative for Multicenter Perioperative Clinical Trials, an arm dedicated to clinical and translational research.

The second group, the National Anesthesia Clinical Outcomes Registry, is maintained by the Anesthesia Quality Institute, a nonprofit organization established by the ASA. This large-scale data warehouse collects paper and electronic anesthesia case data used to review anesthesia practices with the intent of optimizing local efforts to assess both the risk and the quality of care, and for research purposes for the specialty as a whole. The Registry has released data related to perioperative mortality (cited earlier).

OTHER APPROACHES TO DISCERN THE ROOT CAUSE OF MORBIDITY AND MORTALITY

Although mortality directly attributable to anesthesia appears to have declined over time, the exact causes of this decline remain unclear. Numerous factors have been implicated in the improved outcome, including new monitoring modalities, new anesthetic drugs, and changes in the anesthesia workforce. However, relating the reduced risk to any one factor on the basis of available epidemiologic data is difficult. Further, although the use of newer monitoring modalities, particularly pulse oximetry, would be expected to improve outcomes, no randomized trial has been able to document such a conclusion. This limitation supports the need for continued monitoring of complications and their root cause through a number of approaches.

Initiated by the Professional Liability Committee of the ASA, the ASA-CCP represents one important approach to understanding the root causes of important complications of anesthesia care. The ASA-CCP constitutes an ongoing, nationwide survey of closed insurance claims for major anesthesia-related adverse events. In an early publication based on data collected by the ASA-CCP, Caplan and colleagues reviewed both fatal and nonfatal outcomes resulting in claims against anesthesia providers. Among the fatal events, unexpected cardiac arrest during spinal anesthesia was observed in 14 healthy patients from the initial 900 claims.[81] These cases were analyzed in detail to identify patterns of care that might have led to the event. Two patterns were identified: oversedation leading to respiratory insufficiency and inappropriate resuscitation of high spinal sympathetic blockade.

Tinker and co-workers[82] queried the ASA-CCP to determine the role of monitoring devices in the prevention of anesthesia mishaps. They reviewed 1097 anesthesia-related claims and determined that 31.5% of the negative outcomes could have been prevented by the use of additional monitors, primarily pulse oximetry and capnography. Injuries that were deemed preventable with additional monitoring resulted in dramatically more severe injury and cost of settlement than did those judged to be nonpreventable with additional monitoring. These findings were reinforced by a subsequent study of intraoperative respiratory events by Caplan and colleagues (Table 30.10).[83] These claims represented the single largest class of injury (34%), with death or brain damage occurring in 85% of cases. They identified inadequate ventilation, esophageal intubation, and difficult tracheal intubation as the primary causes of respiratory events. The investigators believed most of the outcomes to be preventable with better monitoring, such as pulse oximetry or capnography (Fig. 30.4).[84] In more recent evaluations of MAC using the ASA-CCP, more than 40% of 121 claims associated with MAC involved death or permanent brain damage. Respiratory depression, after an absolute or relative overdose of sedative or opioid drugs, was the most common (21%, $n = 25$) of the complications.

A similar registry was developed by the Danish Patient Insurance Association.[85] For the years of 1996 through 2004, 1256 files were related to anesthesia, and 24 deaths were considered to be a result of the anesthetic procedure: 4 deaths were related to airway management, 2 to ventilation management, 4 to central venous catheter placement, 4 as a result of medication errors, 4 from infusion pump problems, and 4 after complications from regional blockade. Severe hemorrhage caused one death, and the cause was uncertain in one case.

TABLE 30.10 Distribution of Adverse Respiratory Events in the American Society of Anesthesiologists' Anesthesia Closed Claims Study

Event	Number of Cases	Percent of 522 Respiratory Claims
Inadequate ventilation	196	38
Esophageal intubation	94	18
Difficult tracheal intubation	87	17
Inadequate inspired oxygen concentration	11	2

From Caplan RA, Ward RJ, Posner K, Cheney FW. Unexpected cardiac arrest during spinal anesthesia: a closed claims analysis of predisposing factors. *Anesthesiology*. 1998;68(1):5–11.

Cooper and colleagues[86,87] took an alternate approach to examining perioperative mortality through the study of critical incidents, which were defined as those that were potentially preventable and could lead to undesirable outcomes. This definition included events that led to no harm or only transient effects. The investigation involved collecting data on anesthesia-related human errors and equipment failures from anesthesiologists, residents, and certified registered nurse anesthetists (CRNAs). In a series of reports, the authors identified frequent incidents, such as disconnections in breathing circuits, and causes of discovery of errors, such as intraoperative relief. They confirmed that equipment failure was a small cause of anesthesia mishaps (4%), whereas human error was a predominant factor. They suggested that future studies of anesthesia-related mortality and morbidity should classify events according to a strategy for prevention rather than outcome alone.

Other countries have developed similar databases, such as the Australian Incident Monitoring Study. Data from this database have been used to evaluate problems with ventilation, with vascular access, and in the PACU.[88,89]

ISSUES ASSOCIATED WITH ANESTHESIA-RELATED MORTALITY

The studies detailed in the preceding text focus on intraoperative or in-hospital deaths directly attributable to anesthesia care; nonetheless, perioperative complications may contribute to the risk of mortality beyond the immediate postoperative period. For example, a perioperative stroke or myocardial infarction may lead to death after the period of analysis. Notably, recent research has suggested that even small myocardial infarctions or unstable angina during the perioperative period have been associated with worsened long-term survival.[91] Should these *late* deaths be attributed to anesthesia complications for the purpose of such analyses? The answer depends on the outcome and its relationship to anesthesia management.

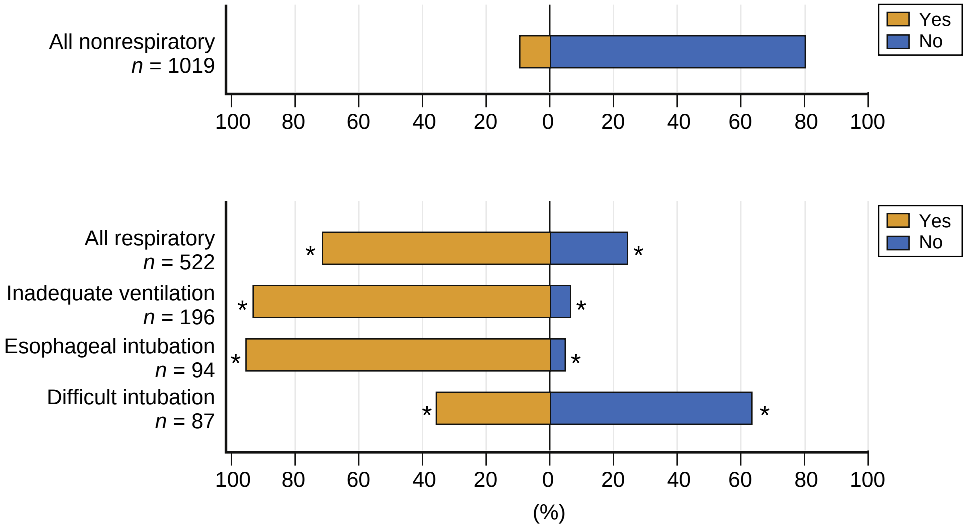

Fig. 30.4 Relationship between adverse events in the American Society of Anesthesiologists' Anesthesia Closed Claims Project and preventable complications. Preventable events related to respiratory complications were significantly more common than those related to all nonrespiratory complications. Of the respiratory complications, difficult intubation had the least number of preventable complications (*$P < .05$ vs. nonrespiratory claims). (From Caplan RA, Posner KL, Ward RJ, Cheney FW. Adverse respiratory events in anesthesia: a closed claims analysis. *Anesthesiology*. 1990;72(5):828–833.)

The potential effects of anesthesia on long-term survival were suggested by Monk and colleagues.[92] Using multivariate Cox proportional hazards models, these investigators identified three variables as significant independent predictors of mortality: patient comorbidity (RR, 16.116), cumulative deep hypnotic time (bispectral index < 45) (RR, 1.244/h), and intraoperative systolic hypotension (RR, 1.036/min). Further work is required to determine whether these results reflect a true pathophysiologic link between perioperative (anesthesia) management and long-term outcome or a simple statistical association. This study and others, however, emphasize the importance of evaluating all aspects of anesthesia care and short- and long-term outcomes to try to optimize both long- and short-term patient outcomes.

Risks Related to Patient Characteristics

Multiple studies have demonstrated that perioperative morbidity and mortality are increased in the presence of coexisting medical diseases. The ASA physical status classification system, originally proposed in 1941,[93] represents a widely used method of classifying the severity of coexisting disease among surgical patients. Since its introduction, this classification system has established a standardized terminology for anesthesia practice and has aided in developing valid statistical comparisons of outcomes among sites.[94]

The correlation between ASA physical status and mortality offers a simple illustration of the link between comorbidities and adverse operative outcomes. In 1961, Dripps and co-workers demonstrated that mortality increased as the severity of comorbid disease increased, as assessed by the ASA physical status classification.[32] Several investigators have reevaluated the relationship between operative mortality and ASA physical status and demonstrated similar findings.[43,46,95]

In Canada, Cohen and colleagues[96] analyzed 100,000 anesthesia procedures and determined mortality within 7 days of surgery by using governmental vital statistics mortality data between the years 1975 and 1984. For each patient, information was collected on age, preoperative conditions, ASA physical status, anesthetic technique, monitors, and other factors. The overall 7-day mortality rate was 71.04 deaths per 10,000 procedures. Risk markers for mortality are detailed in Table 30.11.

TABLE 30.11 Risk Factors Associated With Increased Odds of Dying Within 7 Days For All Cases

Variable	All Procedures: Relative Odds of Dying Within 7 Days	95% Confidence Limits
PATIENT RELATED		
Age (yr)		
60-79 vs. < 60	2.32	1.70-3.17
80+ vs. < 60	3.29	2.18-4.96
Sex (female vs. male)	0.77	0.59-1.00
ASA physical status classification (3-5 vs. 1-2)	10.65	7.59-14.85
SURGERY RELATED		
Major vs. minor	3.82	2.50-5.93
Intermediate vs. minor	1.76	1.24-2.5
Length of anesthesia (≤2 h vs. < 2 h)	1.08	0.77-1.50
Emergency vs. elective	4.44	3.38-5.83
OTHER FACTORS		
Year of surgery (1975-1979 vs. 1980-1984)	1.75	1.32-2.31
Complication in the surgical or recovery unit (yes vs. no)	1.42	1.06-1.89
ANESTHESIA RELATED*		
Experience of the anesthetist (>600 procedures for ≥ 8 years vs. <600 procedures for <8 years)	1.06	0.82-1.37
Inhalation with narcotic vs. inhalation alone	0.76	0.51-1.15
Narcotic alone vs. inhalation alone	1.41	1.01-2.00
Narcotic with inhalation vs. inhalation alone	0.79	0.47-1.32
Spinal vs. inhalation alone	0.53	0.29-0.98
Number of anesthetic drugs (1-2 vs. 3)	2.94	2.20-3.84

*All cases performed with the five most frequently used anesthetic techniques.

Modified from Cohen MM, Duncan PG, Tate RB. Does anesthesia contribute to operative mortality? *JAMA*. 1988;260(19):2859–2863.

One of the limitations of the ASA physical status classification system is that the ranking is determined by individual anesthesia providers; as such, there may be variance between providers, as demonstrated by Owens and coworkers.[97] In light of these limitations, other studies have attempted to define the specific patient characteristics that are most strongly associated with perioperative adverse events related to a particular organ system. In evaluating the risk directly related to the patient's condition, the limitations of the methodology must be understood. All such studies evaluate the predictive value of a clinical or laboratory risk factor for a defined perioperative complication. In this approach, a cohort of individuals of interest is defined. Ideally, the study is performed prospectively, and the outcome of interest is assessed in a rigorous, blinded fashion. Despite this, many available studies of perioperative risk factors focus on selected patients and include a retrospective design, methods that greatly limit their generalizability and validity. Many studies use multivariate modeling to determine the factors associated with increased risk. A major limitation in the use of multivariate modeling for this purpose is the assumption that the intraoperative period is a *black box* and that care is not modified by the knowledge of the risk factor (Fig. 30.5). However, anesthesiologists modify intraoperative care of high-risk patients in an attempt to minimize the likelihood of complications. Changes in medical care over time and better knowledge about high-risk patients should result in a reduction of the risk related to specified clinical factors. Such considerations make it difficult to design and complete formal investigations to validate individual management strategies in the context of current practice.

One common approach taken in past efforts to quantify operative risk has been to examine the relationship between a single risk factor and a broad range of adverse perioperative outcomes. For example, numerous studies have evaluated the importance of hypertension on perioperative risk. Goldman

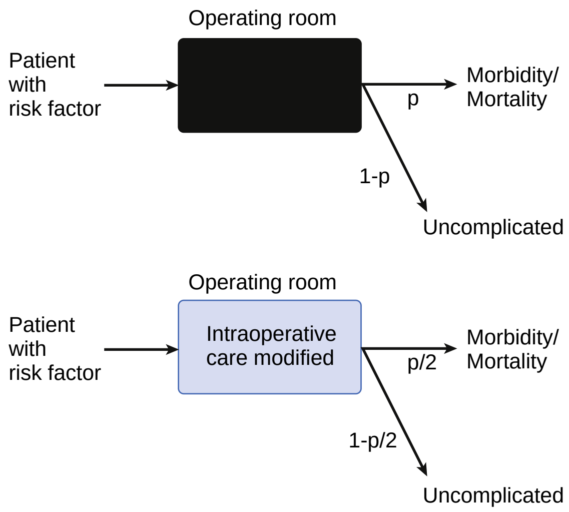

Fig. 30.5 The concept of the black box for risk indices. In developing a risk index, patients with a specific risk factor enter the operating room and have a complication at a rate *p*. If the anesthesiologist is aware of the importance of the risk factor and can modify care to reduce such risk (*p/2*), then the risk factor may no longer be significant. If the risk factor is ignored, then complications may again occur in such patients.

and Caldera[98] evaluated a cohort of patients undergoing noncardiac surgery under general anesthesia. Hypertension was not associated with increased perioperative risk, although the number of patients with diastolic blood pressure greater than 110 mm Hg was too small to draw any statistically significant conclusions. In contrast, Hollenberg and co-workers[99] identified hypertension and the presence of left ventricular hypertrophy as predictors of perioperative ischemia, but they did not consider their independent relationship to perioperative major morbidity. More recently, Baron and colleagues[99a] analyzed data from a prospective study examining perioperative care across 28 European countries to evaluate the impact of hemoglobin levels on in-hospital mortality. Patients with severe (hemoglobin < 8 g/dL) or moderate (8-11 g/dL) levels were found to have higher rates of in-hospital mortality as well as longer length of stay and a higher likelihood of postoperative admission to the intensive care unit.

An alternative to examining the impact of a single risk factor on perioperative outcomes involves a more general effort to identify multiple risk factors for one or more adverse perioperative outcomes. Multiple researchers have undertaken prospective and retrospective cohort studies with the goal of identifying patients at greatest risk for fatal and nonfatal myocardial infarction. One of the earliest attempts to define cardiac risk was performed by Goldman and colleagues at the Massachusetts General Hospital.[13] They studied 1001 patients older than 45 years of age who were undergoing noncardiac surgery. Using multivariate logistic regression, they demonstrated nine clinical factors associated with increased morbidity and mortality. Each risk factor was weighted in the logistic regression equation and converted into points in the index. An increasing number of points was associated with increasing perioperative cardiac morbidity or mortality.

Several attempts have been made to validate the Goldman Cardiac Risk Index in the surgical population.[100,101] The validity of the Cardiac Risk Index is more controversial for patients undergoing vascular surgery. Several groups[102-104] were able to demonstrate a similar, if not identical, pattern of increasing cardiac complication rate with increasing cardiac risk. Several other studies, however, were unable to demonstrate any relationship between the Cardiac Risk Index and perioperative cardiac complications, with a high incidence of complications found in patients with a Cardiac Risk Index of I or II.[105,106] When the ASA physical status classification system was compared with the Goldman Cardiac Risk Index in a cohort of 16,277 patients undergoing noncardiac surgery,[106] both indices demonstrated predictive value, although the objective Goldman Cardiac Risk Index provided little additional value over the more subjective ASA physical status classification.

Since the introduction of the Goldman Cardiac Risk Index, other investigators have put forward alternative risk indices for cardiac events after noncardiac surgery, such as the Detsky Modified Risk Index,[107] which confirms many of the factors identified by Goldman and allows calculation of a pretest probability of complications based on the type of surgery, after which the Detsky Modified Risk Index is applied with the use of a nomogram. The Detsky Modified Risk Index was advocated as the starting point for risk stratification in the American College of Physicians guidelines on preoperative evaluation.[108] Lee and colleagues[109] created a Revised Cardiac Risk Index (RCRI) incorporating six additional risk factors identified in a single-institution study: high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine level higher than 2.0 mg/dL. The rate of major cardiac complications increased with the number of risk factors. The performance of the RCRI was examined in a metaanalysis conducted by Ford and colleagues,[110] who found that although the RCRI showed moderate discrimination for patients at low versus high risk for cardiac events after noncardiac surgery, it did not perform well at predicting death or at predicting cardiac events after vascular surgery.

Gupta and colleagues[111] used data collected by the NSQIP to evaluate the risk for cardiovascular events after noncardiac surgery. This model, which included five variables—type of surgery, dependent functional status, abnormal creatinine level, ASA physical status, and increasing age—demonstrated improved discrimination over the RCRI, which did not improve with the addition of the RCRI score to the model.

Vascular Events in Noncardiac Surgery Patients Cohort Evaluation Study (VISION) is a multinational cohort group actively investigating major perioperative vascular events and their impact on mortality. In a 2016 study of over 15,000 patients in 12 countries, Berwanger and colleagues[111a] noted a reduction in risk of a composite outcome of all-cause mortality, myocardial injury after noncardiac surgery (MINS), and stroke at 30 days (RR = 0.83, 95% CI 0.40-0.83, P = .007) associated with preoperative statin use. Perioperative statin use was also associated with a reduction in all-cause mortality, cardiovascular mortality, and MINS; however, there was no statistically significant difference in risk of myocardial infarction or stroke in statin users or non-users.

In a secondary analysis of the same patient cohort, Abbot and group[111b] investigated the association between elevated heart rate preoperatively and MINS within 30 days of surgery. Preoperative heart rate was stratified by deciles. The results showed that 7.9% of participants had sustained MINS, 2.8% myocardial infarction, and 2.0% died. After adjusting for confounders, the highest heart rate decile (preoperative heart rate more than 96 beats/min) was associated with increased risk of perioperative MINS (odds ratio 1.48, $P < .01$), MI (odds ratio 1.71, $P < .01$), and mortality (odds ratio 3.16, $P < .01$). Heart rates in the lowest decline (<60 beats/min) were independently associated with reduced mortality (odds ratio 0.05, $P = .02$). In a second subgroup analysis, preoperative hypercoagulability was associated with a higher risk of MINS.[111c]

Beyond the efforts at identifying those patients most at risk of postoperative cardiovascular events, recent research has sought to develop statistical models for a range of other organ-based preoperative outcomes. These have included risk models for acute kidney injury in cardiac[112] and noncardiac surgery patients,[60] postoperative respiratory failure,[113,114] and stroke after cardiac surgery[115] and carotid endarterectomy.[116]

In contrast to the efforts to determine risk factors for specific organ-based complications, other investigators have sought to develop risk-prediction models to identify those patients at risk of death from any cause in the immediate postoperative period. For example, Glance and colleagues from the University of Rochester used data from the NSQIP to derive and validate a predictive score for 30-day all-cause mortality for noncardiac surgery. They identified three factors that were highly predictive of death at 30 days after surgery: (1) ASA physical status, (2) emergency status, and (3) surgery type. Patients with ASA physical status I, II, III, IV, or V were assigned 0, 2, 4, 5, or 6 points, respectively; intermediate- or high-risk procedures were assigned 1 or 2 points, respectively; and emergency procedures were assigned 1 point. Patients with risk scores less than 5 had a predicted risk of mortality less than 0.5%, whereas patients with a risk score of 5 to 6 had a risk of mortality between 1.5% and 4%. Patients with a risk score greater than 6 had risk of mortality more than 10%.[117]

Beyond their clinical applicability, such risk indices have become important in the context of health policy by allowing for comparisons of risk-adjusted mortality rates across hospitals and physicians providing cardiac surgery. For example, the state of New York annually publishes data on mortality rates associated with coronary bypass grafting by surgeon and by hospital.[118-120] For comparison of rates across institutions, institutional mortality rates are typically risk-adjusted so that high-performing institutions that treat a high percentage of medically complex patients are not spuriously categorized as *poor performers* simply because of the features of their patient mix.

Beyond identifying clinical indicators of perioperative risk, historic and current research has focused on the role of genetics and genomics on the outcomes of major surgical procedures. Notably, the impact of genotype on perioperative risk has been well known since elucidation of the inheritance pattern of malignant hyperthermia. With malignant hyperthermia, a clear link exists between the autosomal dominant disease and an adverse outcome after administration of an anesthetic.[121] Interest in evaluating the impact of genetic polymorphism on overall perioperative outcome is increasing, even if the link to anesthesia is less well defined. For example, apolipoprotein E4 has been shown to modulate neurologic injury and recovery after a variety of acute ischemic insults, including coronary artery bypass grafting.[122] Polymorphism of the glycoprotein IIIa constituent of the platelet integrin receptor has also been correlated with postoperative cognitive decline.[123,124] Further research will be required to determine specific genetic profiles that will impact anesthetic management strategies, drug selection, and other aspects of care.

Special Patient Groups

OBSTETRICS

Anesthesia for the obstetric patient carries unique challenges, since both the mother and the fetus are potentially at risk for complications. Fortunately, maternal mortality is rare, and the anesthesia-related component of maternal delivery represents only a small fraction of all maternal deaths. As a result, studies of peripartum complications require a large number of patients from a diversity of clinical settings.

In parallel to the early efforts to determine the overall risk of anesthesia for surgery, a series of studies were performed between 1974 and 1985 that sought to determine the rate of obstetric complications in the United States and England, and to assess the contribution of anesthesia per se to the risk of adverse events in this group. Kaunitz and coauthors[125] reported an anesthesia-related death rate of 0.6 per 100,000 births with data from all 50 states. Endler and coworkers[126] studied births in Michigan between 1972 and 1984 and found a rate of 0.82 anesthesia-related deaths per 100,000 live births. Eleven of the 15 deaths were associated with cesarean section. Obesity and emergency surgery were risk factors in many patients. Complications related to regional anesthesia were identified as a problem in the earlier years of the study, whereas failure to secure a patent airway was the primary cause of mortality in the later years. No anesthesia-related maternal deaths occurred in the final 2 years of the study. Rochat and colleagues[127] studied 19 areas of the United States between 1980 and 1985 and reported 0.98 anesthesia-related deaths per 100,000 live births. They observed that maternal mortality did not decrease over the time of the study.

The Confidential Enquiry into Maternal Deaths in England and Wales has been assessing maternal deaths since 1952.[128] Morgan[128] reported the maternal deaths from anesthesia between 1952 and 1981 (Table 30.12). The total maternal mortality rate decreased over time, but the percentage of deaths related to anesthesia increased, although the absolute number of deaths associated with anesthesia decreased. Later reports identified technical difficulties with intubation as a major risk factor. The other major finding of this study was that the experience of the anesthesia provider in obstetric anesthesia was the most important factor in anesthesia-related maternal mortality.

More recent investigations have confirmed ongoing decreases over time in the hazards of obstetric anesthesia. Hawkins and associates[129] obtained data from the ongoing National Pregnancy Mortality Surveillance System of the

Centers for Disease Control and Prevention on births and fetal deaths from 1979 through 1990 to determine the possible risk related to anesthesia for obstetrics. They identified a total of 129 women who died of anesthesia-related causes during the study period. Most (82%) of the deaths occurred during cesarean section, and the incidence of anesthesia-related maternal mortality decreased over time (Table 30.13), possibly the result of a trend toward a greater use of neuraxial techniques. Importantly, among maternal deaths that occurred in the context of general anesthesia for cesarean delivery, 73% were related to airway problems.

In a subsequent study, Panchal and colleagues[130] conducted a retrospective case-control study using patients' records from a state-maintained anonymous database of deliveries between 1984 and 1997. Of the 822,591 hospital admissions for delivery during the 14-year study period, 135 maternal deaths occurred. The most common diagnoses associated with mortality during hospital admission for delivery were preeclampsia or eclampsia (22.2%), postpartum hemorrhage or obstetric shock (22.2%), pulmonary complications (14%), blood clot or amniotic embolism or both (8.1%), and anesthesia-related complications (5.2%). Notably, Panchal's study recorded differences by race in the rate of maternal death per 100,000 live births per year (Fig. 30.6). Although the potential causes of this difference remain to be elucidated, Panchal's findings also suggested potential improvements over time in both the overall risk of maternal mortality, as well as the degree to which such risk differed by race.

TABLE 30.12 Maternal Mortality Figures Obtained from the Confidential Enquiry into Maternal Deaths in England and Wales

Years	Maternal Mortality Per 1000 Total Births	Number of Deaths from Anesthesia	Percent of True Maternal Deaths from Anesthesia	Percent With Avoidable Factors
1952-1954	0.53	49	4.5	—
1955-1957	0.43	31	3.6	77
1958-1960	0.33	30	4.0	80
1961-1963	0.26	28	4.0	50
1964-1966	0.20	50	8.7	48
1967-1969	0.16	50	10.9	68
1970-1972	0.13	37	10.4	76
1973-1975	0.11	31	13.2	90
1976-1978	0.11	30	13.2	93
1979-1981	0.11	22	12.2	100

From Morgan M. Anaesthetic contribution to maternal mortality. *Br J Anaesth*. 1987;59(7):842–855.

More recent studies have continued to portray maternal mortality related to anesthesia as an important, although exceedingly rare event. Importantly, contemporary analyses of adverse maternal outcomes of anesthesia emphasize the particular risks associated with airway management in this population.[131,132] In 2004, the Society for Obstetric Anesthesia and Perinatology established the Serious Complication Repository Project to better capture the incidence of serious complications related to obstetric anesthesia. D'Angelo and colleagues[132A] collected outcomes of over 257,000 anesthetics at 30 institutions over a 5-year period. They identified a total of 157 serious complications, 85 of which were anesthesia-related (1 major complication per 3000 anesthetics). Maternal death occurred in 30 cases, but none were determined to be anesthesia-related. Complications frequently attributable to anesthesia included high neuraxial block, respiratory arrest, and unrecognized intrathecal catheter (Table 30.14).

In summary, extensive past research has indicated that the risks of major morbidity and mortality attributable to obstetric anesthesia care have decreased over time; nonetheless, recent research indicates that adverse outcomes continue to occur and may be of particular concern for patients receiving general anesthesia for cesarean delivery. As these risks are quantified with increasing precision using large databases, further research will be needed to validate these findings and identify the impact of variable care delivery (including the use of differing anesthetic techniques) and the maternal outcomes across institutions and practice environments.

PEDIATRICS

There are few studies of anesthesia-related risk in the pediatric population. Several themes emerge from these studies: very young infants are at increased risk of mortality, and anesthesia-related risk is reduced in centers with specialized pediatric anesthesia facilities. More recently, attempts have been made to define the neurocognitive risks presented by exposure to anesthesia at a young age.

In Beecher and Todd's classic 1954 study on anesthesia outcomes,[18] a "disproportionate number" of anesthesia-related deaths occurred in children younger than 10 years of age. Similarly, Graff and colleagues[133] from the Baltimore Anesthesia Study Committee reported 335 operative deaths

TABLE 30.13 Numbers, Case Fatality Rates, and Risk Ratios of Anesthesia-Related Deaths During Cesarean Section Delivery by Type of Anesthesia in the United States, 1979 to 1984 and 1985 to 1990

in the pediatric age group. Of these, 58 were thought to be primarily or partially attributable to anesthesia. The percentage of operative deaths attributable to anesthesia was relatively constant among age groups at 16.6% to 21.7%. The studies that followed those of Beecher and Todd and the Baltimore Anesthesia Study Committee provided further detail on the risks associated with pediatric anesthesia over time. Tiret and coauthors[134] prospectively studied major anesthesia-related complications in pediatric patients in 440 hospitals in France between 1978 and 1982. There were 27 major complications in 40,240 cases, which included 12 cardiac arrests and 1 death. The incidence of major complications and cardiac arrest was significantly higher in infants than in older children. Most complications in infants involved the respiratory system and predominantly consisted of airway problems and aspiration. Older children experienced respiratory and cardiac complications, which occurred most frequently during induction and recovery.

Cohen and colleagues[135] studied 29,220 anesthesia procedures at the Winnipeg Children's Hospital in the 1980s. Data on patients' coexisting medical conditions and postoperative follow-up were obtained within 72 hours. Complications included death, cardiac arrest, drug reactions, airway

TABLE 30.15 Summary of Perioperative Events by Age Group

[‡] Percentage of total anesthetics in which at least one event occurred in the intraoperative unit, recovery unit, or later during the postoperative period.

All figures are given as the percentage of events per total anesthetics.

Modified from Cohen MM, Cameron CB, Duncan PG. Pediatric anesthesia morbidity and mortality in the perioperative period. *Anesth Analg*. 1990;70(2):160–167.

obstruction, and minor complications such as nausea and vomiting, arrhythmias, and sore throat. Neonates underwent a higher percentage of major vascular or cardiac and intraabdominal procedures, and older children had a higher incidence of extremity procedures. Intraoperative cardiac arrest occurred most frequently in patients younger than 1 year of age (4 in 2901 procedures). Postoperatively, minor events such as nausea and vomiting were more common in older children, whereas respiratory events were more common in infants and younger children (Table 30.15). When compared with adult patients, children experienced different complications, which frequently extended well into the postoperative period. In a comparison of 2-year periods between 1982 and 1987, rates of intraoperative events were found to be stable, and the rate of postoperative complications decreased.

More recently, van der Griend and colleagues reported on 24-hour and 30-day mortality associated with 101,885 anesthetics administered to 56,263 children at the Royal Children's Hospital in Melbourne, Australia. They noted a rate of all-cause 24-hour mortality of 13.4 per 10,000 anesthetics and a 30-day all-cause mortality of 34.5 per 10,000 anesthetics. The incidence of deaths related to anesthesia was far lower, occurring at a rate of 1 in 10,188 or 0.98 cases per 10,000 anesthetics performed. In all of the 10 anesthetic-related deaths that the authors observed, preexisting medical conditions were assessed to have been a significant contributing factor.[136]

In contrast to efforts to determine the incidence and predictors of mortality among pediatric surgical patients, a number of investigators have focused on cardiac arrest in the context of pediatric anesthesia. For example, Flick and associates[137] studied patients younger than 18 years of age who underwent surgery at the Mayo Clinic and experienced perioperative cardiac arrest between November 1, 1988 and June 30, 2005. A total of 92,881 anesthetics were administered during the study period, 4242 (5%) of which were for the repair of congenital heart malformations. The incidence of perioperative cardiac arrest during noncardiac procedures was 2.9 per 10,000, and the incidence during cardiac procedures was 127 per 10,000. The incidence of perioperative cardiac arrest attributable to anesthesia was 0.65 per 10,000 anesthetics. The incidence of cardiac arrest and mortality was highest in neonates (0 to 30 days of life) undergoing cardiac procedures (incidence, 435 per 10,000; mortality, 389 per 10,000).

Investigators at the Children's Hospital of Boston conducted a registry study to evaluate rates of arrest in patients undergoing surgery for congenital heart disease.[138] Over a 5-year period, 41 cardiac arrests occurred in 40 patients during 5213 anesthetics for an overall frequency of 0.79%. Eleven cardiac arrests (26.8%) were classified as either likely ($n = 6$) or possibly related ($n = 5$) to anesthesia (21.1 per 10,000 anesthetics) but with no mortality.

Efforts to understand the causes and outcomes of cardiac arrest in pediatric anesthesia patients have been aided by the development of large-scale clinical registries for research and quality improvement. In 1994, the Pediatric Perioperative Cardiac Arrest (POCA) Registry[139] was formed to determine the clinical factors and outcomes associated with cardiac arrest in anesthetized children. A total of 289 cardiac arrests occurred in the 63 institutions in the database during the first 4 years of the registry, 150 of which were judged to be related to anesthesia (1.4 per 10,000 anesthesia procedures), with a 26% mortality rate. Medication-related causes and cardiovascular causes of cardiac arrest were most common. Anesthesia-related cardiac arrest occurred most often in patients younger than age 1 year and in patients with severe underlying disease. In 2007, an update from the POCA registry was published.[140] From 1998 through 2004, 193 arrests (49%) were related to anesthesia. Cardiovascular causes of cardiac arrest (41%) were the most common, with hypovolemia from blood loss and hyperkalemia from transfusion of stored blood being the most common identifiable cardiovascular causes (Fig. 30.7). In contrast to the earlier study, medication-related arrests only accounted for 18% of all arrests.

In 2010, POCA investigators reported on anesthesia-related cardiac arrest in children with preexisting cardiac disease, comparing 245 cardiac arrests in children without heart disease with 127 cardiac arrests in children with cardiac conditions. Compared with children without cardiac disease, children with cardiac conditions were more often ASA physical status III, IV, or V and more often arrested from cardiovascular causes. Mortality was higher in children with heart disease than among children without heart

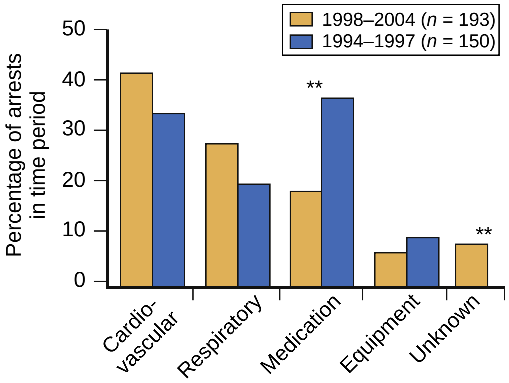

Fig. 30.7 Causes of anesthesia-related cardiac arrest in the Pediatric Perioperative Cardiac Arrest (POCA). Registry from 1998 to 2004 versus 1994 to 1997. (**$P < .01$ 1998-2004 vs 1994-1997 by Z test). (From Bhananker SM, Ramamoorthy C, Geiduschek JM, et al. Anesthesia-related cardiac arrest in children: update from the Pediatric Perioperative Cardiac Arrest Registry. *Anesth Analg.* 2007;105(2):344–350.)

disease (33% vs. 23%) but did not differ when adjusted for ASA physical status classification.[141]

In recent years, researchers have become increasingly interested in how anesthetic exposure in young children impacts neurocognitive development. In 2016, Sun and group[141a] published a sibling-matched cohort study conducted over 4 years at four university hospitals in the United States. They enrolled a total of 105 sibling pairs, one of whom had been exposed to inhalational anesthetics for an inguinal hernia repair before 36 months of age. Neurocognitive testing performed on both siblings did not demonstrate a statistically significant difference in intelligence quotient. Another group (Ing and colleagues)[141b] analyzed data from the Western Australia Pregnancy Cohort to evaluate the relationship between anesthetic exposure in children younger than 3 years of age and neuropsychological, academic, and behavioral outcomes in a cohort of 2868 children. They identified discrepancies in neuropsychological test and ICD-9 coded clinical outcomes, but did not identify any differences in academic achievement, and suggest that the unique attributes of specific tests may explain the variation in cognitive outcomes described in different studies. In another cohort study, Backeljauw and colleagues[141c] matched 5- to 18-year-old participants in a language development study who had undergone surgery with anesthesia before age 4 with unexposed peers. They found that exposed subjects had statistically significantly lower scores in listening comprehension and performance intelligence quotient, and that these changes were associated with lower gray matter density in key brain regions (occipital cortex and cerebellum). Given these conflicting results, further research is clearly needed to evaluate and quantify this impact in more detail.

OLDER ADULTS

The relationship of age to operative risk has been a subject of scientific and clinical debate since the early days of modern surgery. The nature of operative and anesthetic risk in older patients remains a vital area of inquiry particularly as the proportion of U.S. adults 65 years of age and older is anticipated to increase rapidly over the next three decades.

A key issue in research on the safety of surgery and anesthesia among older adults is the determination of what constitutes *old age* from the perspective of perioperative risk. Multiple definitions have been used for advanced age, including age older than 65, 70, 80, or 90 years. Denney and Denson[142] evaluated risk associated with surgery in patients older than 90 years of age. They reported 272 patients undergoing 301 operations at the University of Southern California Medical Center, finding a high perioperative mortality rate among older patients with serious bowel obstruction (63%). Taking a slightly different approach, Djokovic and Hedley-Whyte[143] studied outcome after surgery in 500 patients older than 80 years of age. They found that mortality was predicted by ASA physical status classification, with greater comorbid conditions associated with increasing risk. Myocardial infarction was the leading cause of postoperative death. Patients without significant comorbid diseases (ASA I classification) had a mortality rate of less than 1%.

Del Guercio and Cohn[144] investigated the value of preoperative invasive monitoring in obtaining hemodynamic and cardiopulmonary variables for predicting operative risk in the older adult. Among 148 consecutive patients older than 65 years of age who were treated in a surgical ICU, only 13.5% had normal physiologic measurements. Advanced and uncorrectable functional deficits were found in 63% of patients, and all in this group who underwent the planned surgery died.

Del Guerico and Cohn's work represented one of several studies that emphasized coexisting diseases, rather than aging itself, as the cause of apparently increased perioperative mortality among older adults. More recently, a growing body of literature has focused on the importance of functional disability and chronic geriatric syndromes, such as frailty and dementia, as determinants of postoperative outcomes among older individuals. Robinson and colleagues examined a cohort of 110 surgical patients with a mean age of 74 years, finding a 15% 6-month rate of mortality. Statistically significant predictors of 6-month mortality included impaired cognition, a recent fall, hypoalbuminemia, anemia, functional dependence, and comorbidity. Notably, functional dependence was the strongest predictor of 6-month mortality. Four or more markers in any one patient effectively predicted 6-month mortality (sensitivity, 81%; specificity, 86%).[145] Finlayson and colleagues observed high rates of mortality after major gastrointestinal surgery among older nursing home residents versus the overall Medicare population; the high rates of mortality were likely attributable to high rates of comorbidity and functional disability within this population.[146]

In this context, research on the risks of surgery and anesthesia in the older adult now focuses on broader definitions of *risk* that include functional outcomes and quality of life, in addition to traditional morbidity and mortality outcomes. Finlayson and colleagues examined 6822 older nursing home residents undergoing intestinal resections for colon cancer, noting a 53% 1-year mortality rate and a 24% rate of sustained decline in functional independence in activities of daily living among survivors. In multivariate regression, age older than 80 years, hospital readmission after surgical discharge, surgical complications, and functional decline before surgery all predicted functional decline at 1 year.[147]

As the older population continues to grow, researchers have recently begun to evaluate the neurocognitive impact of anesthesia on the elderly.

The measures of outcome relative to patient goals of care are becoming increasingly important in determining optimal strategies for perioperative management of the geriatric population. The ASA recently instituted a Perioperative Brain Health Initiative (Fleisher)[147a] dedicated to exploring the potential relationship between anesthetic exposure and postoperative cognitive function and delirium. This topic is discussed in more detail in Chapter 83.

Risks Directly Related to the Anesthetic Drug

Numerous studies have evaluated the influence of the choice of anesthetic on outcome, a question that is discussed throughout this book. From a global perspective, there does not appear to be a single best anesthesia technique for a particular surgery or group of surgeries, although emerging evidence begs for more research on this subject. In a multivariate analysis by Cohen and co-workers[96] of 100,000 anesthesia procedures performed in Canada, the choice of drug did not provide any additional prognostic information for predicting mortality beyond that of patient disease and the surgical procedure. In univariate analysis, MAC appeared to be associated with worse outcomes; however, this association was attributable to the use of MAC in sicker patients (see Table 30.11).

One question that has persisted within the anesthesia literature is the issue of whether anesthetic medications carry inherent toxicity. For example, numerous discussions have focused on the potential toxicity of halothane and sevoflurane. In the case of halothane, concern focused on the potential for fulminant, potentially fatal, hepatic necrosis with this medication. After several case reports of hepatic necrosis after halothane anesthesia, a large retrospective study of 856,500 anesthesia procedures at 34 institutions was undertaken.[148-150] In all but seven cases, hepatic necrosis could be explained by other causes. Halothane could be associated with hepatitis and hepatic failure, but the incidence was very low.

In the case of sevoflurane, concern has centered on the potential nephrotoxicity of its metabolite compound A. Although some laboratory studies have supported the contention that sevoflurane reacts with soda lime to form compound A and that this metabolite can lead to renal toxicity,[151,152] clinical studies have been unable to confirm this potentially detrimental effect[153,154] in the United States.

Some research groups have recently sought to identify and quantify other anesthesia-attributable effects. In 2016, Wigmore and colleagues[154a] published the results of a retrospective cohort study evaluating survival and recurrence outcomes in propensity-matched patients undergoing primary resection of malignancy with inhaled versus intravenous anesthetics in over 7000 patients in the United Kingdom. After adjusting for confounders, the investigators demonstrated a hazard ratio of 1.46 for death in patients receiving volatile anesthetic versus those receiving inhalational agents, a result which demands further prospective investigation.

In 2008, the GALA investigators[154b] published results of a randomized controlled trial comparing outcomes following carotid endarterectomy with local versus general anesthesia in 3526 patients with asymptomatic or symptomatic carotid stenosis. Primary outcomes included stroke, myocardial reinfarction, and 30-day mortality. Of the patients undergoing general anesthesia 4.8% experienced events, as compared to 4.5% of patients who were managed with local anesthetics (3 events preventable per 1000 treated). The investigators were not able to identify a statistically significant benefit to local or general anesthesia for individual primary outcomes, or for 30-day quality of life, hospital length of stay, or surgical duration. In a retrospective cohort study published in 2015, van den Berg and colleagues[154c] investigated outcomes of intraarterial treatment of patients with acute ischemic stroke with or without general anesthesia. Cases without general anesthesia were associated with good clinical outcome in a higher proportion than those treated with general anesthesia (26% vs. 14%), although there were notable distinctions between the two groups. They also found a nonsignificant mortality benefit in the non-general anesthesia group. The authors speculated that anesthetics might alter autoregulation of cerebral blood flow; however, their results were confounded by the determination that arterial recanalization was delayed by up to 20 minutes in patients undergoing interventions with general anesthesia.

Numerous studies have attempted to define the *safest* anesthetic for high-risk patients. In the late 1980s, there was concern that isoflurane caused coronary steal in patients with coronary stenosis and collaterals and that this could result in myocardial ischemia.[155,156] A series of studies were conducted to evaluate the rate of perioperative cardiac morbidity and mortality in patients undergoing coronary artery bypass grafting to determine the importance of the agent used for general anesthesia.[157-160] Taken together, these studies demonstrated negligible differences in outcome, thus supporting the contention that multiple safe approaches to general anesthesia may exist for an individual context. Other studies have focused on the relative safety of general anesthesia versus neuraxial or regional techniques (Basques et al.).[161,162,162a] For lower extremity and pelvic surgery, regional anesthesia was associated with a lower incidence of graft thrombosis and deep venous thrombosis, as well as decreased bleeding, decreased length of stay (Neuman et al.),[162b] reduced risk of surgical site infection, and risk of prolonged hospitalization (Helwani et al.).[162c] Regional anesthesia has also been specifically associated with lower major complication rates in patients with OSA (Memtsoudis et al.).[162d] In a more recent meta-analysis published by O'Donnell and colleagues,[162e] the findings were less favorable. Although they were able to determine a small difference in hospital length of stay attributable to regional anesthesia, the discrepancies in outcome reporting among the different studies were such that they were not able to identify definitively any other differences between the two approaches. The investigators of two randomized controlled trials currently underway, REGAIN (Neuman et al.)[162f] and RAGA-delirium, (Li et al.)[162g] are attempting to quantify the impact of anesthetic choice on morbidity, mortality, and cognitive outcomes in patients undergoing hip fracture surgery.

For patients undergoing vascular surgery, the primary finding favoring regional anesthesia was a lower incidence of graft thrombosis and the need for reoperation in patients undergoing infrainguinal bypass surgery; however, the largest of these studies was unable to demonstrate any difference in outcome based on anesthesia technique.[163-165] The rate of this complication was low in the total cohort in the largest trial, which made it impossible to detect any difference based on technique. Summarizing findings from several of these studies, Rodgers and co-workers[162] published an influential meta-analysis of regional versus general anesthesia. Neuraxial blockade was found to reduce postoperative mortality and other serious complications. As such, the magnitude of some of these benefits remained uncertain. Discussion of regional versus general anesthesia is presented in Chapters 45 and 46.

The impact of perioperative ventilation modality has also recently come under investigation: in 2015, Ladha's group[165a] published a hospital-based registry study examining outcomes of 69,239 patients undergoing noncardiac surgery requiring endotracheal intubation. Roughly 50% of patients received a protective ventilation strategy (reduced tidal volume and high positive end-expiratory pressure [PEEP]) versus standard care. Protective ventilation, defined as a PEEP of 5 cm H_2O and a plateau pressure of 16 cm H_2O or less, was associated with a reduced risk of postoperative respiratory complications. High driving pressure and plateau pressure were associated with an increased risk of respiratory complications. Severgnini and colleagues[165b] randomized 56 patients undergoing elective open abdominal surgery to a standard mechanical ventilation strategy (tidal volume of 9 mL/kg, ideal body weight [IBW], and zero PEEP), or "lung protective" ventilation (7 mL/kg, IBW, PEEP of 10 cm H_2O, recruitment maneuvers). Patients receiving protective ventilation demonstrated respiratory function and reduced Clinical Pulmonary Infection Score for several days postoperatively. Length of stay did not differ between groups.

Risks Related to Surgery

The surgical procedure itself significantly influences perioperative risk. In virtually every study performed, emergency surgery is associated with additional risk. [98] In some cases, the risk related to surgery is a function of the underlying disease processes and the stress related to the surgical procedure. As a category of surgical procedures, cardiovascular surgery has historically been associated with the highest risk of mortality and major morbidity. (The risks related to anesthesia for cardiac surgical procedures are reviewed in Chapter 54.) Vascular surgery is among the highest-risk group of noncardiac procedures. Although aortic reconstructive surgery has traditionally been considered the procedure with the highest risk, infrainguinal procedures have shown a similar rate of cardiac morbidity in several studies, possibly due to a higher burden of coronary artery disease in this population.[166,167] Other high-risk vascular procedures include amputation.[168] Intraabdominal, thoracic, and orthopedic procedures have also been associated with increased risk.[13,168]

Eagle and associates[170] evaluated perioperative cardiac morbidity and mortality among patients who had been treated for coronary artery disease and subsequently underwent major noncardiac surgery. Among these patients, major vascular surgery was associated with the highest risk of myocardial infarction or death, with a combined incidence of morbidity and mortality greater than 5%. Procedures associated with a combined complication rate of 1% to 5% included intraabdominal, thoracic, and head and neck surgical procedures. Low-risk procedures included breast, skin, urologic, and orthopedic surgeries. Ultimately, these groupings of surgical procedures came to form the basis for the definitions of surgical risk published in the American College of Cardiology/American Heart Association joint guidelines on perioperative cardiovascular evaluation for noncardiac surgery.[171] More recent statistical modeling efforts, such as those of Gupta[111] and Glance,[117] aimed at predicting postoperative outcomes have reinforced the important contribution of the type of surgical procedure to the overall operative risk.

Studies of the perioperative complication rate related to superficial procedures are generally reassuring. Backer and associates[172] evaluated the rate of perioperative myocardial reinfarction in patients who have a history of preexisting coronary artery disease and who underwent ophthalmologic surgery. They demonstrated that the rate of perioperative cardiac morbidity after ophthalmologic surgery was extremely low, even in patients with a recent myocardial infarction. Similar findings have been reported by multiple other investigators.[69,173]

More recent work suggests that surgical duration may also affect perioperative risk. Kim and group[173a] reviewed a cohort of over 1 million patients undergoing surgery under general anesthesia between 2005 and 2011 and demonstrated an association between surgery duration and the risk of development of venous thromboembolism. These results were preserved in analysis of individual procedures and classes of procedure by specialty.

Risks Related to the Location of Surgery and Postoperative Monitoring

Perioperative risk varies among hospitals for major procedures such as coronary artery bypass grafting and abdominal aortic aneurysm repair.[9,10,174] Multiple studies have documented a relationship between surgical volume and mortality. Although surgical skill most certainly plays a role in the rate of complications and mortality, local factors may also play an important role. For example, low surgical volume may lead to less skilled anesthesia and postoperative care. The influence of each of these factors on overall morbidity and mortality is unknown.

Although the value of postoperative monitoring and care in an ICU has never been documented in a randomized clinical trial, many investigators have suggested that such care is one of the primary reasons for the improved morbidity and mortality in recent years. For patients undergoing major vascular surgery, several investigators have suggested that more intense postoperative monitoring could obviate the need for preoperative cardiac testing and revascularization.[171] One potential value of risk assessment is the identification of patients who could benefit from referral to clinical centers with more extensive perioperative resources. Patients with a low probability of perioperative morbidity and mortality could have surgery performed locally, and individuals at higher risk could receive benefit from transfer to a center with high surgical volume.

Risks Related to the Anesthesia Provider

Over the past decade a great deal of attention has been paid to the role and skill of the anesthesia provider on patient outcome. Historically, anesthesia has been administered by a diverse group of providers with variable levels of supervision. The extent to which the skills and training of the individual anesthesia provider may affect outcomes has been assessed in a number of studies. In a now-classic paper, Slogoff and Keats[175] studied the association of perioperative myocardial ischemia and cardiac morbidity in patients undergoing coronary artery bypass grafting across multiple anesthesiologists working in a single practice. Notably, the rate of perioperative ischemia and infarction varied by anesthesiologist, and the authors concluded that operator technique and experience may affect risk. Subsequent work has moved beyond efforts to demonstrate variability in anesthesia outcomes at the level of the individual practitioner to examine whether outcomes might vary across different models of anesthesia care. Arbous and coauthors reported a case-control study over 1 year in the Netherlands,[176] in which they found that practice-level independent variables associated with a decreased risk for coma and death in 24 hours were (1) anesthesia equipment check performed with a checklist; (2) direct availability of an anesthesiologist by telephone, beeper, or walkie-talkie during maintenance anesthesia; (3) no change of anesthesiologist during the case; (4) presence of a full-time nurse anesthetist versus a part-time anesthetist during maintenance anesthesia; and (5) presence of two providers versus one person during emergence. This study was one of very few that attempted to identify practice characteristics rather than specific drugs or techniques that have an impact on anesthesia outcomes, and the results are striking, in spite of numerous issues with data reporting and matching. The finding that practitioner characteristics affect outcomes warrants further follow-up.

Attention has recently turned to the impact of handoffs of anesthesia care on patient outcomes. In 2018, Jones and colleagues[176a] published a retrospective cohort study evaluating outcomes including all-cause mortality, hospital readmission, and major postoperative complications in 313,066 patients undergoing major surgery. They identified an association between complete anesthesia handoffs (i.e., when one provider or team leaves the case permanently and is replaced by another) and increased incidence of primary outcomes, as well as with increased rates of ICU admission and hospital length of stay. The study design was limited by the inability to control for the career experience of the replacement anesthesiologist and surgeon as well as by the sole use of billing codes to determine exposure to a transition in anesthesia care.

Several studies have attempted to evaluate the complication rates and risks associated with various care provider models. Bechtoldt,[177] as a member of the North Carolina Anesthesia Study Committee, evaluated 900 perioperative deaths that occurred in an estimated 2 million anesthesia procedures performed in North Carolina between 1969 and 1976. The lowest rate of anesthesia-related deaths (1 per 28,166 procedures) occurred in patients who received anesthesia from an anesthesia care team (physician anesthesiologist and CRNA), and the highest rate (1 per 11,432 procedures) was associated with anesthesia administered by a dentist; the rate for the nurse anesthetist–only cohort was intermediate (1 per 20,723). A study by the Stanford Center for Health Care Research[178] demonstrated similar outcomes: the investigators reported that death plus severe morbidity was 11% higher than predicted in patients who received their care in a nurse anesthetist–only setting, 3% lower than predicted for physician-only care, and 20% lower than predicted for an anesthesia care team environment. Both studies demonstrated significant methodologic limitations.

The impact of specific provider types may be greatest in particular situations: for example, patients with significant comorbid diseases and those who sustain perioperative complications may benefit from providers with specific skill sets. One way to study such issues is to evaluate the rate of survival after complications. Silber and colleagues[7] at the University of Pennsylvania studied the medical records of 5972 surgical patients randomly selected from 531 hospitals. They evaluated patient and hospital characteristics, including the number and type of physicians, board certification status, and ratio of care providers. The 30-day mortality rate correlated with patient characteristics. Failure to rescue (i.e., failure to prevent death) after an adverse event was inversely associated with the proportion of board-certified anesthesiologists on staff in each facility. Improved perioperative survival was significantly associated with the presence of an increased number of board-certified anesthesiologists. These findings were corroborated in follow-up studies by the same group,[179,181] wherein analysis was again limited by database characteristics.[181] By contrast, Pine and co-workers evaluated mortality after eight specific surgical procedures[182] and used stepwise logistic regression to derive procedure-specific risk adjustment models. They found hospitals without anesthesiologists had results similar to those facilities in which anesthesiologists provided or directed anesthesia care. The authors did not evaluate failure to rescue or cause of mortality.

More recently, work by Needleman and Minnick compared obstetric outcomes in facilities with different obstetric anesthesia staffing patterns.[183] Although the authors observed consistent differences in maternal mortality and other quality indicators at facilities where nurse anesthetists practiced with minimal or no supervision by anesthesiologists versus anesthesiologist-only facilities, questions regarding risk adjustment and study design limit definitive interpretations of this work for policy making.[184] Similarly, a 2010 study by Dulisse and Cromwell suggested no changes in overall surgical patient outcomes in states that had enacted laws allowing nurse anesthetists to practice independently versus states that required anesthesiologist supervision.[185] However, as such new

BOX 30.1 Proposed Definitions from the 1984 International Symposium on Preventable Anesthesia Morbidity and Mortality

Outcome
  Normal
  Abandoned procedure
  Morbidity
  Death
Morbidity
  Unplanned, unwanted, undesirable consequence of anesthesia
Mortality
  Death that occurs before recovery from the effects of a drug or drugs given to facilitate a procedure
  Death that occurs during an attempt to relieve the pain of a condition
  Death that results from an incident that occurs while the drugs are effective

Modified from Pierce EC Jr. The 34th Rovenstine Lecture. 40 years behind the mask: safety revisited. *Anesthesiology*. 1996;84(4):965–975.

legislation was not associated with major changes in the number or types of surgery conducted without anesthesiologist supervision, Dulisse and Cromwell's work does not speak directly to the question of the gains or losses in safety associated with any specific provider type for a given type of surgery.

Ultimately, as concluded by Smith and associates[186] in a review of available published studies through 2004 on the influence of anesthesia providers, the relationship of patient outcomes to the type of anesthesia provider has not yet been conclusively demonstrated. Nurse anesthetists and other nonphysician providers are vital to the delivery of anesthesia care in the United States and elsewhere, and determining the optimal scope of practice for such providers remains an ongoing area of academic research and political debate.

Improving Anesthesia Safety

Over the past several decades, major improvements to the safety of anesthesia have been initiated. In 1984, Cooper, Kitz, and Pierce hosted a landmark International Symposium on Preventable Anesthesia Mortality and Morbidity in Boston. Approximately 50 anesthesiologists from around the world attended the meeting and, after much debate, established a series of definitions of outcome, morbidity, and mortality (Box 30.1). Beyond its specific conclusions, however, the symposium remains an event of major historical importance as a seminal early event in the movement to improve patient safety and as the context out of which the Anesthesia Patient Safety Foundation (APSF) was established. After its formal incorporation in October 1985, the APSF has since actively promoted a range of initiatives focused on fulfilling its mission to continually improve the safety of patients during anesthesia care by encouraging and conducting: (1) safety research and education, (2) patient safety programs and campaigns, and (3) national and international exchange of information and ideas. To this end, the APSF has focused on promoting research, practice improvement, and knowledge dissemination across a range of priority areas (Box 30.2). Overall, these efforts have stressed the potential for systems-level improvements, standardization of care processes, human-factors engineering, and simulation-based training to limit harms caused by preventable adverse events and errors in crisis management in the context of anesthesia care. Through this work, the APSF has come to serve as a leader in patient safety, not only in the context of anesthesia and perioperative care, but also more generally within medicine by establishing *patient safety* as a formal concept, discipline in medical care, and serving as a model for other organizations such as the U.S. National Patient Safety Foundation.[197]

Alongside the efforts of the APSF, other prominent organizations, such as the ASA, have sought to improve the safety of anesthesia care through the creation and dissemination of standards and guidelines for clinical practice.

BOX 30.2 Selected Areas of Focus of the Anesthesia Patient Safety Foundation, 1985 to 2012

- Use of anesthesia simulators for training and evaluation
- Improvement of standards for intraoperative monitoring
- Application of patient safety checklists to intraoperative care
- Promotion of standardized approaches to difficult airway management
- Prevention of medication-related adverse events
- Reuse and attempted resterilization of disposable anesthesia equipment
- Risks of outdated anesthesia machines without modern safety features
- Aiding the development of practice standards by the World Federated Societies of Anesthesiologists
- Surgery department crisis management, including teamwork, team training, and resource management
- *Production pressure*, causing dangerous omissions and cutting corners
- Intravenous procedural sedation by nonanesthesia personnel
- Contamination of medical gases and disruption of pipeline flow
- Contamination of intravenous medications
- Special risks of office-based anesthesia
- Patients with obstructive sleep apnea and their postoperative care
- Postoperative cognitive dysfunction (particularly in older adults)
- Possible long-term increase in morbidity and mortality after extensive general anesthesia
- Postoperative vision loss, especially in extensive prone spine surgery
- Wrong-site surgery
- Residual neuromuscular blockade and postoperative complications
- Protocols for assessing and managing adverse events
- Persistence of deaths from malignant hyperthermia
- Dangers and challenges in patients with coronary artery stents
- Maintenance of current protocols for the anesthesia machine checkout
- Possible impact of anesthesia management on cancer recurrence
- Persistence of surgical unit fires

Modified from Eichhorn JH. The Anesthesia Patient Safety Foundation at 25: a pioneering success in safety, 25th anniversary provokes reflection, anticipation. *Anesth Analg*. 2012;114(4):791–800.

In general, both standards and guidelines represent summations by clinicians of the available evidence about the benefits and risks of particular approaches to treatment. Typically, a practice standard implies that a therapy or practice should be performed for patients with a particular condition. Standards are approved only if an assessment of the probabilities and utilities of the group indicate that the decision to choose the treatment or a strategy would be virtually unanimous. At present, the ASA has established one set of practice standards for anesthesia care, which outline basic requirements for intraoperative monitoring.[198]

In contrast to practice standards, guidelines are intended to be more flexible than standards, but they should be followed in most cases. Depending on the patient, setting, and other factors, guidelines can and should be tailored to fit individual needs. Similar to standards, guidelines should be cost-effective methods. Specific guidelines have been created by the ASA for diverse issues such as a difficult airway,[199] the use of the pulmonary artery catheter,[200] and the use of blood components[201] with the goal of defining the evidence on which optimal practice can be based. In a similar vein, the World Health Organization has recently placed an emphasis on the potential for a simple preoperative checklist, modeled on the processes used in other high-risk industries such as aviation, to reduce the rates of adverse events in the perioperative period.[202] Driven in part by the findings of improved outcomes with checklist use in a multicenter, international study by Haynes and co-authors,[203] such expanding interest in the use of standardized safety checks offers new potential opportunities to decrease the risk of anesthesia further.

Applying further insights gained from the aviation industry to anesthesia care, the APSF and other organizations have focused on developing simulation-based approaches to train anesthesia providers and to evaluate their decision-making capabilities in crisis situations.[204-208] To date, an extensive array of standardized scenarios have been developed for making comparisons among individuals, and research is ongoing to examine how best to use this technology in anesthesia training and recertification. Ultimately, such efforts, combined with improved monitoring of adverse outcomes through large outcomes databases and those now being assembled by the Multicenter Perioperative Outcomes Group and the Anesthesia Quality Institute, hold potential to improve the safety of anesthesia care continually on both a national and an international level.

Summary

The risks related to anesthesia appear to have dramatically decreased over the past several decades. Clearly, death solely attributable to anesthesia is rare; rather, underlying patient disease and the nature and extent of surgery have a greater effect on overall outcome than do risks attributable to the anesthetic per se. Although these changes in the risk attributable to anesthesia could justifiably be considered a major achievement on the part of anesthesia providers over time, they also present a novel challenge to anesthesia providers to identify new opportunities to aid in more broadly decreasing both the morbidity and the mortality of surgical procedures and to aid in aligning the results of surgical interventions with individual patients' goals of care. At the same time, vigilance must be continued to maintain high standards of basic anesthesia care across both hospital- and nonhospital-based settings. Finally, anesthesia providers should play a role in systems-based thinking to improve perioperative care and the short- and long-term outcomes of patients undergoing surgery and anesthesia.

31 Preoperative Evaluation

DUMINDA N. WIJEYSUNDERA and EMILY FINLAYSON

KEY POINTS

- The anesthesia preoperative evaluation, which is the clinical foundation for guiding perioperative patient management, reduces perioperative morbidity and enhances patient outcome.
- The fundamental purpose of preoperative evaluation is to obtain pertinent information regarding the patient's medical history, formulate an assessment of the patient's perioperative risk, and develop a plan for any requisite clinical optimization.
- The preanesthesia evaluation should include a focused clinical examination, documentation of comorbid illness, reduction of patients' anxiety through education, assurance that preexisting medical conditions are optimally managed, selective referrals to medical specialists, ordering of preoperative investigations, initiation of interventions intended to decrease risk, discussion of aspects of perioperative care, arrangements for appropriate postoperative care, and recommendations to delay or cancel the surgical procedure, if deemed appropriate.
- Comorbid medical diseases can influence anesthesia and perioperative management, thus requiring the anesthesiologist to be knowledgeable in many aspects of internal medicine.
- Patients require appropriate preoperative diagnostic and laboratory studies consistent with their medical history and the proposed surgical procedure. Routine preoperative testing cannot be justified because it is costly and often clinically inappropriate.
- The anesthesiologist-led preoperative evaluation outpatient clinic can enhance operating room efficiency, decrease day-of-surgery cancellations or delays, reduce hospital costs, and enhance the quality of patient care.
- New and updated preoperative evaluation consensus and evidence-based guidelines published by multiple medical specialties have important influences on the preparation of patients for anesthesia and surgery.
- Anesthesiologists must be aware of, and be compliant with, increasing regulatory and reporting requirements involving preoperative issues by healthcare agencies.
- The anesthesiologist is the perioperative medical specialist and thus is uniquely positioned to evaluate the risks associated with anesthesia or surgery, discuss these risks with the patient, and manage them perioperatively in collaboration with the surgical team, referring physician, and other medical specialists.

Preoperative evaluation is required prior to the administration of any anesthetic. Its practice and scope have changed dramatically. Initial changes were driven by a rapid transformation in practice from hospital admission of patients the night before surgical procedures to admission on the morning of surgery. More recently, preanesthesia evaluation has become integral to the Perioperative Surgical Home model that aims to develop an integrated model for managing the entire perioperative episode of care.[1] This evolution in practice has led to a new approach to preoperative evaluation, which is a vital role of the perioperative physician. Accordingly, many anesthesiologists have expanded their responsibilities from providers of intraoperative anesthesia care to *perioperative medical specialists* who use their unique knowledge and experience to manage medical complexities related to surgery.[2] This expanded role entails that anesthesiologists assume the leadership role in the assessment and optimization of patients who are scheduled for surgery.[3] This chapter provides a comprehensive discussion of the practice of preoperative evaluation, as well as a review of related concepts, current evidence, and consensus-based clinical practice guidelines.

Evolution of Preanesthesia Evaluation

All patients requiring anesthesia for surgery must undergo a preoperative evaluation by their anesthesia provider. The conduct of this evaluation has changed substantially. Historically, anesthesiologists assessed their patients for the first time either just before the surgical procedure or on the preceding day, with the remainder of preoperative evaluation and preparation being the responsibility of the surgeon, primary care provider, or other specialist. In some countries, this approach remains the usual clinical practice. Nonetheless, in many countries, anesthesiologists have increasingly taken on a leadership role in preoperative evaluation and preparation, well in advance of the scheduled procedure. This is particularly true for high-risk patients or those undergoing high-risk procedures.

Several factors explain this change. First, considerably fewer patients are admitted to the hospital prior to the day of surgery. In many countries, there is little financial justification for the previous model of admitting patients prior to the day of surgery. For example, most surgical procedures in the United States are performed on an outpatient or same-day admission basis, including major neurosurgical, cardiac, and cancer resection procedures. Second, surgical patients are increasingly likely to be older frail individuals with significant burdens of medical comorbidity.[4] For such patients, sufficient time is needed between the preanesthesia evaluation and the planned surgery to facilitate testing, interventions, and medical optimization. In the case of patients with very high-risk medical comorbidity, preoperative consultation by an anesthesiologist can help inform a shared decision-making process for proceeding with surgery (see section on "Frailty, Geriatric Conditions, and the Older Surgical Patient"). Third, anesthesia care increasingly extends beyond the operating room alone. Preoperative evaluation is an integral component of the anesthesiologists' role as perioperative physicians who are involved in integrated medical care before, during, and after surgery. The specialty is uniquely positioned for this role given its expertise in the management of medical complexities related to anesthesia and surgery. This view of preoperative evaluation as a key component of the integrated management of the entire perioperative episode of care is essential to the Perioperative Surgical Home model.[1]

Outpatient preoperative assessment clinics have been instrumental in facilitating greater involvement of anesthesiologists in preoperative evaluation. These clinics also impose new clinical and organizational challenges. In an institution where most surgical patients are evaluated in the preoperative assessment clinic, anesthesiologists may have less time to evaluate medically complex patients. Consequently, anesthesiologists must achieve a high level of efficiency and accuracy in the assessment of a patient's history, physical examination, and differential diagnosis, as well as in the planning of perioperative management. Conversely, in a hospital where only the highest-risk patients are referred for consultation at a preoperative assessment clinic, the anesthesia department must interact with surgical departments to establish general protocols that ensure capture of the information needed to perform anesthesia safely, as well as the appropriate selection of individuals who require preoperative anesthesia consultation. In addition to changes in the scope and timing of the preanesthesia evaluation, this assessment has increasingly been influenced and governed by practice guidelines. For example, in the United States, The Joint Commission mandates documentation of a history and physical examination for any surgical patient within 30 days before the planned procedure, as well as reassessment within the 48-hour period immediately preceding the surgical procedure. The American Society of Anesthesiologists (ASA) and European Society of Anaesthesiology (ESA) have published specific guidelines for preoperative anesthesia evaluation.[5,6] In addition, several other specialty societies published practice guidelines specifically relating to the preoperative management of medical issues in surgical patients.[7-12]

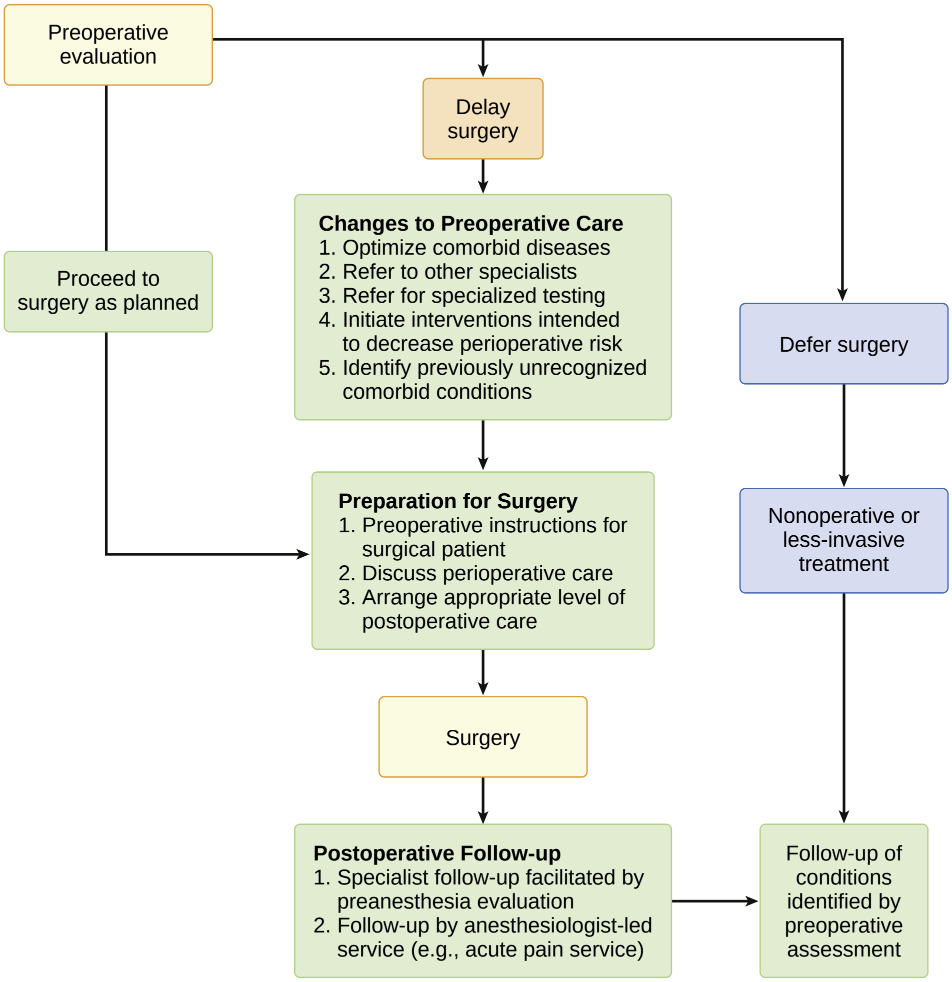
Goals and Benefits of Preanesthesia Evaluation

Preoperative evaluations help influence and improve perioperative care (Fig. 31.1). Indeed, inadequate preoperative evaluation was a contributing factor in 3% of perioperative adverse events in the Australian Incident Monitoring Study database.[13] The overarching goals of preanesthesia evaluation are to (1) ensure that the patient can safely tolerate anesthesia for the planned surgery; and (2) mitigate perioperative risks such as pulmonary or cardiovascular complications. In pursuit of these goals, preanesthesia evaluations offer opportunities to perform focused clinical examinations, better document comorbid illness, reduce the patient's (and family's) anxiety through education, optimize preexisting medical conditions, make selective referrals to medical specialists (e.g., cardiologists), order specialized investigations (e.g., cardiac stress tests), initiate interventions intended to decrease risk, discuss aspects of perioperative care (e.g., anticipated risks, fasting guidelines), and arrange appropriate levels of postoperative care (e.g., critical care unit). If a patient is deemed to be at very high risk for adverse perioperative outcomes, the anesthesiologist may also recommend consideration of a nonoperative or less invasive treatment. Such a recommendation helps inform shared decision making for surgery (see Clinical Examination During Preoperative Evaluation section). In some cases, preanesthesia evaluation can identify a previously unrecognized medical condition (e.g., hypertension) that may not significantly affect perioperative risks, but warrants longer-term follow-up by appropriate healthcare professionals.

Compared to preoperative evaluations performed by surgeons or primary care physicians alone, anesthesiologist-led preoperative evaluation is associated with more selective ordering of laboratory tests and referral to specialists, thereby leading to reduced healthcare costs.[14-17] Within the context of an anesthesiologist-led preoperative evaluation clinic, preanesthesia evaluations also associated with reduced anxiety,[18] improved acceptance of regional anesthesia,[19] fewer day-of-surgery case cancellations,[14,20-22] shorter hospital length-of-stay,[19,21,22] and lower hospital costs.[21]

Clinical Examination During Preoperative Evaluation

The *clinical examination*, consisting of the history and physical examination, is a fundamental component of preoperative evaluation by anesthesiologists. This information helps identify the underlying basis for the planned surgery, clarify the extent of comorbidities with specific perioperative relevance, identify opportunities for preoperative optimization, and select any appropriate preoperative testing. The consistency and quality of preoperative examinations are enhanced through standardization. Specifically, the baseline clinical examination of all surgical patients should include a consistent



Preoperative evaluation
Delay surgery
Changes to Preoperative Care
1. Optimize comorbid diseases
2. Refer to other specialists
3. Refer for specialized testing
4. Initiate interventions intended to decrease perioperative risk
5. Identify previously unrecognized comorbid conditions
Proceed to surgery as planned
Defer surgery
Preparation for Surgery
1. Preoperative instructions for surgical patient
2. Discuss perioperative care
3. Arrange appropriate level of postoperative care
Nonoperative or less-invasive treatment
Surgery
Postoperative Follow-up
1. Specialist follow-up facilitated by preanesthesia evaluation
2. Follow-up by anesthesiologist-led service (e.g., acute pain service)
Follow-up of conditions identified by preoperative assessment

Fig. 31.1 Mechanisms by which preoperative evaluation can help influence and improve perioperative care.

set of components,[23] with opportunities for more detailed examination of one or more of these components (e.g., cardiovascular system) based on the findings from the standardized initial examination. Computer-based preoperative evaluation tools offer a mechanism for improving the standardization of high-quality preoperative assessments,[24,25] and are recommended in the 2018 ESA guidelines on preoperative evaluation.[6] The quality of the preoperative physical examination is further enhanced by appropriately considering evidence-based implications of different findings.[26]

COMPONENTS OF THE MEDICAL HISTORY

The important components of the anesthesia history are presented in the sample preoperative history form in Fig. 31.2. This information can be documented, either on paper or an electronic form, by anesthesia staff during an in-person or telephone interview with the patient. Alternatively, the patient can complete a form capturing the required information, either in person or remotely through a web-based program. The preanesthesia evaluation starts with the planned surgery and its indication. The development of the underlying condition necessitating surgery (e.g., cancer) and any prior related therapies need to be evident. Current known medical problems, past medical issues, previous surgeries, anesthesia types, and anesthesia-related complications must be noted. A simple notation of diseases or symptoms such as hypertension, diabetes mellitus, ischemic heart disease, shortness of breath, or chest pain is not sufficient. Rather, their associated severity, stability, associated activity limitations, exacerbations (current or recent), prior treatments, and planned interventions should be clearly documented. All related diagnostic test results, interventions, and names of treating physicians should be reviewed. The patient's responses to these initial questions may elicit further inquiry to establish a complete history.

Prescription and over-the-counter medications (including supplements and herbal medications) should be documented, along with their dosages and schedules. This information should include any recently interrupted medications with perioperative implications (e.g., recent corticosteroid therapy). The anesthesiologist should list any allergies to medications and other substances (e.g., latex, radiographic dye), with special emphasis on the patient's response to the exposure.

Patients often claim an "allergy" to a substance when, in reality, the reaction was an expected side effect (e.g., nausea or vomiting with narcotics). Tobacco, alcohol, or illicit drug use must be documented. Tobacco exposure is best quantified using pack-years (number of packs of cigarettes smoked per day, multiplied by the number of years of smoking); as an example, an individual who smoked two packs of cigarettes daily for the prior 10 years is deemed to have a 20 pack-year history of tobacco use. A personal or family history of pseudocholinesterase deficiency and malignant hyperthermia (including a suggestive history such as hyperthermia or rigidity during anesthesia) must be clearly documented to facilitate appropriate planning before the day of surgery. Information from previous anesthetic records may clarify an uncertain history.

A standardized general review of all organ systems should then be performed. For example, patients should be asked whether they ever had problems with their heart, lungs, kidneys, liver, and nervous system. In addition, they should be asked about any history of cancer, anemia, bleeding problems, or prior hospitalization for any reason. The principal emphasis should be on airway abnormalities, anesthesia-related adverse events (personal or family history), as well as symptoms of cardiovascular, pulmonary, hepatic, renal, endocrine, or

neurologic disease. For example, a report of a patient who has experienced excessive sore throat, dental injuries, or "the need to have a small tube" with previous anesthetic cases may be an indication of previous difficulty with airway management. A history of snoring and daytime somnolence may suggest undiagnosed sleep apnea (see later section on "Obstructive Sleep Apnea"). Any history of chest discomfort (including its duration, precipitating factors, associated symptoms, and relieving factors) could be important. Similarly, a list of previous surgical procedures should be obtained and can help complete the medical history. Finally, records from primary care physicians, specialists, or inpatient admissions may reveal any issues the patient did not recall.

ASSESSMENT OF FUNCTIONAL CAPACITY

The assessment of the patient's cardiopulmonary fitness or functional capacity is an integral component of the preoperative clinical examination. This information is typically used to estimate a patient's risk for major postoperative morbidity or mortality, and to determine whether further preoperative testing is required.[7] Importantly, suboptimal functional capacity is common in many economically advanced countries. For example, only one-fifth of American adults meet federal guidelines for recommended levels of aerobic and strengthening activity.[27] Poor exercise capacity and cardiopulmonary disease have a bidirectional relationship. Specifically, lack of exercise may increase the risk of developing cardiopulmonary disease but preexisting cardiopulmonary disease can also prevent an individual from exercising. For example, patients with peripheral artery disease (PAD) may be limited by intermittent claudication, and patients with ischemic heart disease may be limited by exertional chest discomfort. There is a reasonable body of evidence demonstrating an association between poor preoperative functional capacity and increased perioperative risk. Most of these studies involved objective assessment of preoperative functional capacity using either exercise testing or cardiopulmonary exercise testing (CPET).[28-31] Several other large studies have demonstrated association between very significant preoperative functional impairment (i.e., difficulty or inability to perform activities of daily living) and increased risks of postoperative mortality,[32] cardiovascular complications,[33] and pulmonary complications,[34,35]

The challenge with assessment of preoperative functional capacity pertains to how best to assess it in usual clinical practice. Typically, the anesthesiologist will inquire about a patient's general activity levels during the preoperative interview, and on that basis, make a *subjective assessment* of the patient's functional capacity. Functional capacity is typically quantified in using the metabolic equivalent of task (MET), where one MET is approximately the rate of energy consumption at rest (3.5 mL/kg/min). A proposed scheme for estimating METs based on information from the preoperative interview is presented in Table 31.1. There are important limitations to the usual clinical approach for this integral component of the preoperative evaluation. First, subjective assessment does not accurately estimate the patient's true exercise capacity. In a multicenter prospective cohort study of 1401 patients undergoing major noncardiac surgery, anesthesiologists' subjective assessment had only 19% sensitivity and 95% specificity for identifying patients' inability to attain 4 or more METs during formal exercise testing.[36] In addition, subjective assessment has poor correlation with standardized questionnaires that have been validated for measuring functional capacity.[37,38] Second, subjective assessment has generally shown poor performance in predicting postoperative morbidity and mortality. In a single-center cohort study of 600 surgical patients, patients' self-reported poor exercise capacity (defined as inability to walk four blocks and climb two flights of stairs) was associated with increased risk of serious perioperative complications,[39] but the magnitude of the association was relatively weak (positive likelihood ratio of 1.3 and negative likelihood ratio of 0.6). For context, positive test results should have likelihood ratios greater than 2 to provide clinically meaningful information, whereas negative test results should have likelihood ratios of less than 0.5.[40] Furthermore, in both a multicenter prospective cohort study and single-center retrospective cohort study, subjective assessment was a poor predictor of postoperative mortality and morbidity.[36,41]

To improve preoperative evaluation of functional capacity, anesthesiologists should consider instead using structured questionnaires, such as the Duke Activity Status Index (DASI) (Table 31.2).[42] This 12-item self-administered questionnaire about activities of daily living has demonstrated correlation with gold-standard measures of functional capacity in surgical patients.[36,43] Furthermore, DASI scores have been shown to improve prediction of postoperative cardiac complications following noncardiac surgery.[36] While there is some varying opinion as to how DASI scores should be converted to METs, the original formula is presented below:

TABLE 31.1 Metabolic Equivalents* of Functional Capacity

METs	Equivalent Level of Exercise
1	Eating, working at computer, or dressing
2	Walking down stairs or in your house, or cooking
3	Walking 1 or 2 blocks on level ground
4	Raking leaves, gardening
5	Climbing 1 flight of stairs, dancing, or bicycling
6	Playing golf, or carrying clubs
7	Playing singles tennis
8	Rapidly climbing stairs, or jogging slowly
9	Jumping rope slowly, or moderate cycling
10	Swimming quickly, running or jogging briskly
11	Skiing cross country, or playing full-court basketball
12	Running rapidly for moderate to long distances

*One metabolic equivalent of task (MET) is the amount of oxygen consumed while sitting at rest, and is equivalent to an oxygen consumption of 3.5 mL/min/kg body weight.

Modified from Jette M, Sidney K, Blumchen G. Metabolic equivalents (METS) in exercise testing, exercise prescription, and evaluation of functional capacity. *Clin Cardiol.* 1990;13:555–565.

$$\text{Estimated METS} = \frac{(0.43 \times \text{DASI score}) + 9.6}{3.5}.$$

Other alternatives for estimating functional capacity include simple exercise tests (e.g., 6-minute walk test, incremental shuttle walk test),[44] exercise testing (e.g., electrocardiogram [ECG] exercise testing), or CPET. If using a standard exercise test (i.e., not CPET), extrapolation from the total treadmill time on a Bruce protocol exercise test results in overestimation of true exercise capacity. More importantly, resting left ventricular ejection fraction should not be used as a proxy measure of functional capacity.[45,46]

PHYSICAL EXAMINATION

At a minimum, the preanesthetic examination should include vital signs (i.e., arterial blood pressure, heart rate, respiratory rate, oxygen saturation), height, and

weight. Body mass index (BMI), which is calculated based on height and weight, is more informative than weight alone in establishing obesity. A scheme for classifying children and adults based on BMI is presented in Table 31.3. Information pertaining to BMI can help identify individuals at risk for difficulties with airway management, and some chronic diseases (e.g., heart disease, diabetes mellitus, obstructive sleep apnea [OSA]). An ideal body weight should also be calculated,[47] using available formulae such as the Devine equation.[48] Information on ideal body weight can better inform dose selection for some anesthesia-related medications, and settings for positive pressure ventilation. Readily available online calculators can be used to quickly determine both BMI and ideal body weight. Patients often have increased arterial blood pressure during the preoperative visit, even without a prior history of hypertension. This finding may be caused by anxiety, or patients having forgotten to take their usual dose of antihypertensive medication. Thus, a single reading during the preoperative evaluation may not reflect the patient's usual blood pressure control. Repeating the blood pressure measurement or obtaining previous readings, either by obtaining medical records (including prior ambulatory blood pressure testing) or asking patients about their "usual" blood pressure measurements are informative. Ideally, the referral documentation from the patient's primary care physician or surgeon should include information on the patient's usual blood pressure readings.[49]

From an anesthesiologist's perspective, inspection of the airway may be the most important component of the physical examination (see Chapter 44). The components of the airway examination are presented in Box 31.1.[50]

BOX 31.1 Components of the Airway Examination

Length of upper incisors (concerning if relatively long)
Condition of the teeth
Relationship of maxillary incisors to mandibular incisors (concerning if there is prominent overbite)
Ability to advance mandibular incisors in front of maxillary incisors (concerning if unable to do this)
Interincisor or intergum (if edentulous) distance (concerning if < 3 cm)
Visibility of the uvula (concerning if Mallampati class is 3 or more)
Shape of uvula (concerning if highly arched or very narrow)
Presence of heavy facial hair
Compliance of the mandibular space (concerning if it is stiff, indurated, occupied by mass, or nonresilient)
Thyromental distance (concerning if < 6 cm)
Length of the neck
Thickness or circumference of the neck
Range of motion of the head and neck (concerning if unable to touch tip of chin to chest or cannot extend neck)

From: Apfelbaum JL, Hagberg CA, Caplan RA, et al. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology*. 2013;118:251–270.

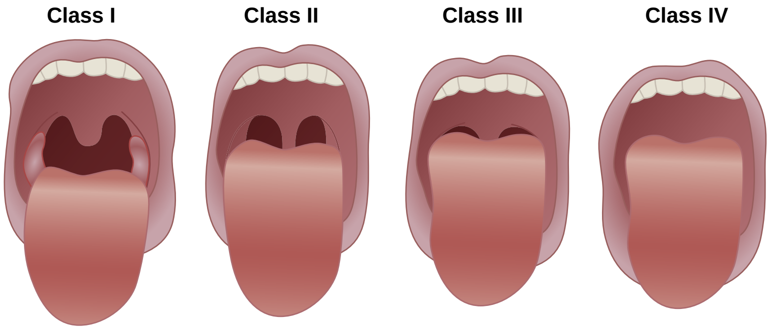

Fig. 31.3 Mallampati classification: class I, soft palate, fauces, entire uvula, pillars; class II, soft palate, fauces, portion of uvula; class III, soft palate, base of uvula; class IV, hard palate only. Fig. 31.4 **Tooth numbering.**

Documentation of an airway examination includes the Mallampati score (Fig. 31.3),[51] status of teeth, degree of neck mobility (especially extension), neck circumference (increased size predicts difficulty with laryngoscopy), thyromental distance, body habitus, and pertinent deformities. Because of the potential for dental injuries during anesthesia, any preexisting tooth abnormalities should be documented (Fig. 31.4). In a French prospective cohort study of 1501 patients, the following characteristics were identified as independent predictors of *difficult* bag-mask ventilation: age more than 55 years, BMI more than 26 kg/m^2, absence of teeth, presence of a beard, and a history of snoring.[52] These risk factors are largely consistent with those identified in an American retrospective cohort study of 22,660 patients: age 57 years or more, BMI 30 kg/m^2 or greater, presence of a beard, Mallampati classification III or IV, severely limited mandibular protrusion, and a history of snoring.[53] Other possible risk factors for difficult ventilation include an increased neck circumference, face and neck deformities (i.e., prior surgery, prior radiation, prior trauma, congenital abnormalities), rheumatoid arthritis, Trisomy 21 (Down syndrome), scleroderma, cervical spine disease, or previous cervical spine surgery. The physical examination must be supplemented by examination of previous anesthetic records, especially when there are indications of a potentially difficult airway. Patients with known difficult airways should be encouraged to obtain medical alert identification. When challenging airways are identified, advance planning ensures that necessary equipment and skilled personnel are available on the day of surgery. An evaluation of the heart, lungs, and skin is necessary, as well as further focus on organ systems involved with diseases reported by the patient. This evaluation should include cardiac auscultation, as well as inspection of arterial pulses, veins (peripheral and central), jugular venous distention, ascites, hepatomegaly, and peripheral edema. Inspection of peripheral veins can also help assess the ease of intravenous access. The auscultatory examination should assess for murmurs, abnormal heart sounds (e.g., third or fourth heart sounds), and pulmonary rales. If intravenous access sites are limited, possible central line placement can be discussed with the patient, or arrangements can be made for assistance from interventional radiology. Auscultation for carotid bruits is also important, especially in patients with a history of stroke, transient ischemic attacks (TIAs), or head and neck irradiation. The presence of a carotid bruit significantly increases the likelihood of an important lesion (i.e., 70%-99% stenosis) in both symptomatic or asymptomatic patients, but the absence of a bruit does not rule out carotid stenosis.[26] Examination of the pulmonary system should include both auscultation (i.e., wheezing, decreased breath sounds, abnormal breath sounds) and inspection (i.e., cyanosis, clubbing, accessory muscle use, respiratory effort). A basic screening neurologic examination should document deficits in mental status, speech, gait, cranial nerve function, motor nerve function, and sensory nerve function. For selected patients (e.g., those with deficits, or scheduled to undergo neurosurgery), a more extensive or focused neurologic examination should document preexisting abnormalities that may aid in diagnosis or interfere with positioning. In addition, the definition of a baseline preoperative neurologic state helps determine whether any postoperative deficits represent new deficits versus preexisting abnormalities.

Frailty, Geriatric Conditions, and the Older Surgical Patient

As patients age, the accumulation of comorbid conditions puts them at increased risk for adverse outcomes after surgery.[54] In addition, geriatric-specific risk factors such as functional and cognitive impairment are associated with poor postoperative outcomes.[54] These clinical conditions, which do not fit into discrete disease categories, are often overlooked in routine preoperative assessments. In order to (1) accurately inform patients of their surgical risk and (2) identify targets for preoperative optimization, assessment of geriatric vulnerabilities is essential before surgery. The American College of Surgeons (ACS) and the American Geriatrics Society (AGS) have established best practice guidelines to guide the preoperative assessment of older surgical patients.[55]

GERIATRIC-FOCUSED ASSESSMENT IN THE OLDER SURGICAL PATIENT

Function and Mobility

Preoperative functional decline is associated with morbidity, mortality, and loss of function after surgery.[54] Assessment of function prior to surgery is consequently essential for risk stratification and postdischarge planning in older surgical patients. Activities-of-daily-living (ADLs) assess the ability to perform basic tasks of selfcare, such as dressing, bathing, toileting, movement, continence, and eating. Instrumental ADLs determine an individual's ability to live independently by the ability to complete shopping, laundry, transportation, finances, medications, food preparation, and housekeeping. To determine additional functional vulnerabilities, determination of vision deficits, hearing deficits, and swallowing difficulties should be routine. Mobility impairment can be efficiently screened by enquiring about a history of falls, determining fall risk, and performing a Timed-Up-And-Go test.[56] The Timed-Up-And-Go test involves timing patients while they perform the following tasks in sequence:

1. Stand up from a chair (without using arm rests if possible)
2. Walk 10 feet
3. Turn around and walk back to chair
4. Sit down in chair

In a prospective cohort of older surgical patients, Timed-Up-And-Go test times were associated with risks of postoperative complications and 1-year mortality in a stepwise fashion.[57]

Cognition

Preoperative cognitive impairment is strongly linked to delirium, complications, functional decline, and death after surgery.[54] The Mini-Cog test (available at https://mini-cog.com), which consists of a three-item recall test and clock draw test, is an efficient tool to screen for preoperative cognitive impairment. Additional information about potential cognitive deficits should be elicited from someone who knows the patient well. Importantly, mild cognitive impairment that is not clinically apparent may have a critical impact on decision-making capacity. Patients should be able to describe, in their own words, the essential elements of the consent discussion—including the surgical condition, indications for surgery, risks, benefits, and alternatives to surgery. It is important to note the four legal criteria for medical decision-making capacity, namely that the patient can (1) clearly indicate his/her treatment choice; (2) understand the relevant information communicated by the physician; (3) acknowledge his/her medical condition, treatment options, and expected outcomes; and (4) engage in a rational discussion about treatment options.[55]

Nutrition

In general, most surgeons and anesthesiologists are keenly aware of the role nutritional status plays in recovery after surgery for all surgical patients. The most common adverse events related to poor nutritional status are infectious complications (i.e., surgical site infections, pneumonia, urinary tract infections), wound complications (i.e., dehiscence, anastomotic leaks), and increased length of stay. [54] The ACS National Surgical Quality Improvement Program (NSQIP) and AGS Best Practice Guidelines recommend the following steps to screen for poor nutritional status (older adults with limited material resources are at particular risk for food insecurity).[55]

1. *Document height, weight, and BMI*

A BMI value less than 18.5 kg/m^2 places an individual at elevated risk and should prompt referral for nutritional assessment.

2. *Measure baseline serum albumin and prealbumin concentrations*

Serum albumin concentration less than 30 g/L (in the absence of hepatic or renal dysfunction) should prompt referral for nutritional assessment.

3. *Inquire about unintentional weight loss in the last year*

Unintentional weight loss exceeding 10% to 15% of baseline weight within the prior 6 months is associated with severe nutritional risk and should prompt referral for nutritional assessment.

Frailty

Frailty, which is defined as a state of increased vulnerability to physiologic stressors, is associated with adverse health outcomes after medical and surgical interventions and

TABLE 31.4 Preoperative Assessment and Optimization in the Older Surgical Patient

Domain	Assessment	Preoperative Optimization
Cognition	▪ Mini-Cog Test ▪ Visual and hearing ▪ Impairment ▪ Alcohol abuse ▪ Medication review	▪ Formal assessment by geriatrician for patient identified to have cognitive impairment on screening ▪ Remind patient to bring all assistive devices (glasses, hearing aids) to hospital ▪ Limit use of sedating or psychotropic medications preoperatively
Function	▪ Evaluate ability to perform activities of daily living and instrumental activities of daily living ▪ Obtain history of falls ▪ Timed up and go test	▪ Refer patients with functional deficiencies or history of falls for formal evaluation by a physical therapist before surgery ▪ Exercise education ▪ Obtain assistive devices ▪ Plan for in-hospital and postdischarge rehabilitation therapy
Nutrition	▪ Document body mass index ▪ Measure albumin and prealbumin ▪ Query unintentional weight loss	▪ Patients at severe malnutritional deficit should be referred to dietician for formal assessment ▪ Preoperative nutritional supplementation and nutrition education

From Oresanya LB, Lyons WL, Finlayson E. Preoperative assessment of the older patient: a narrative review. *JAMA*. 2014;311:2110–2120.

limited life expectancy.[58] Numerous validated instruments measuring frailty are in current use in research and clinical practice. There are two primary models of frailty—the frailty phenotype and the deficit accumulation model. The frailty phenotype described by Fried and colleagues is based on the identification of traits associated with the occurrence of disease, hospitalization, falls, disability, and death in a large prospective cohort study.[59] This study defined the determinants of frailty as weight loss, exhaustion, physical activity, walk time, and grip strength. The deficit accumulation model of aging (based on data from the Canadian Study of Health and Aging) identified 92 signs, symptoms, functional impairments, and laboratory abnormalities that are proportionally weighted into a frailty index for predicting mortality.[60]

While numerous studies have demonstrated the association of patient frailty with adverse surgical outcomes,[54,61-64] the incorporation of a patient's level of frailty into routine clinical practice has not been broadly implemented. Many frailty instruments require special training, input of laboratory values or clinical data, and a fair amount of time to complete; hence, they are impractical in a busy clinical setting. A recent survey of surgical oncologists reported that although most surgeons expressed interest in preoperative optimization for older patients, only 6% currently perform geriatric assessments in their older patients.[65] Factors contributing to the low level of adoption include perceptions regarding the amount of time required to assess for vulnerabilities, and lack of specific programs designed to address them within typical clinical practices. To address this gap, several investigators have validated efficient strategies to measure frailty in clinical practice. Robinson and colleagues developed two alternative frailty assessment definitions for surgical patients,[66,67] which were

- Mini-Cog score of 3 or less, serum albumin concentration of 30 g/L or less, one or more falls in the prior 6 months, and hematocrit under 35%.
- Timed-Up-And-Go test 15 or more seconds, activity-of-daily-living dependence, and Charlson comorbidity index score 3 or greater.[68]

Frailty identified with the Edmonton Frail Scale (EFS) has been shown to be associated with adverse outcomes after surgery.[61] The EFS can be administered by an individual with no formal medical education, and has been validated in comparison to the geriatric specialist's comprehensive geriatric assessment.[69]

Additional Considerations

Anxiety, depression, substance abuse, and social isolation are common underdiagnosed conditions in older adults. Careful screening can identify these potential barriers to recovery, safe discharge after surgery, and maintenance of independence. Up to 11% of the population 71 years of age or more in the United States suffer from depression.[70] The Patient Health Questionnaire-2 is an efficient instrument to screen for depression that includes only two questions: "*In the past 12 months, have you ever had a time when you felt sad, blue, depressed, or down for most of the time for at least two weeks?*" and "*In the past 12 months, have you ever had a time, lasting at least two weeks, when you didn't care about the things that you usually care about or when you didn't enjoy the things that you usually enjoy?*" Among individuals aged 65 years or more, 13% of males and 8% of females consume at least two alcoholic drinks per day.[71] Alcohol and substance abuse are associated with increased rates of postoperative mortality and complications including pneumonia, sepsis, wound infection and disruption, and prolonged length of stay.[72] Consequently, the ACS NSQIP and AGS recommend screening for alcohol and substance abuse among older individuals with the modified CAGE (acronym of four clinical interview questions: cutting down, annoyance by criticism, guilty feeling, and eye-openers) questionnaire (see section on "Patients With a History of Substance Abuse").

PREOPERATIVE OPTIMIZATION FOR FRAIL GERIATRIC PATIENTS (TABLE 31.4)

One goal of the preoperative assessment of elderly surgical patients is to identify potentially modifiable risk factors—such as malnutrition, poor physical function, anxiety, and social isolation—in order to optimize surgical outcomes. Several recent geriatric *prehabilitation* models have emerged to help meet this need, with some demonstrating promising results. One of the first of such programs was the Proactive Care of Older People undergoing surgery (POPS) before-and-after study in United Kingdom.[73] The overarching aim of this project was to decrease complications and hospital length of stay among at-risk older adults undergoing elective surgery. The authors performed a structured geriatric team intervention that identified at-risk patients, and then facilitated coordinated multidisciplinary optimization of geriatric vulnerabilities. The interventions included preoperative home visits by occupational and physical therapists, social worker inputs, nutrition education, and relaxation techniques. In addition to preoperative optimization, interdisciplinary teams participated in daily inpatient rounds, weekly multidisciplinary meetings, and bi-weekly ward rounds led by a consultant or clinical nurse specialist. Compared to historical controls, surgical patients who received the POPS intervention experienced fewer postoperative complications (e.g., pneumonia, delirium), improved pain control, lower rates of delayed mobilization, lower rates of inappropriate urinary catheter use, and shorter hospital length of stay.

Similar findings were observed in the more recently reported Perioperative Optimization of Senior Health study, which was another before-and-after study.[74] This preoperative interdisciplinary clinic evaluated at-risk patients (either aged age ≥ 80 years, or aged ≥ 65 years with concurrent geriatric vulnerability) and designed targeted optimization. Compared to historical controls, the combination of geriatric prehabilitation and inpatient geriatric comanagement were associated with reduced hospital length of stay, reduced readmission rates, and increased rates of discharge to home with self-care. Another example of a promising prehabilitation program is the Michigan Surgical Home and Optimization Program,[75] which is a structured home-based preoperative training program with physical, nutritional, and psychological interventions. The intervention included (1) a home-based walking program with daily reminders and feedback; (2) incentive spirometry instructions starting 1 week prior to surgery; (3) education on nutrition, stress management, and care planning; and (4) resources for smoking cessation, when appropriate. Compared to matched historical controls, patients enrolled in the program experienced reductions in both hospital length of stay and healthcare costs. While promising, these studies do have methodological weakness as before-and-after studies, as opposed to methodologically more robust parallel arm randomized trials, cluster randomized trials, or stepped-wedge trials (see Chapter 90). Nonetheless, the consistency in findings across the studies is supportive of the notion that attention to preoperative and perioperative assessment in the older population can result in improved postoperative outcomes that benefit patients, hospitals, and healthcare systems.

DECISION MAKING FOR SURGERY IN OLDER ADULTS

The critical initial step in surgical decision making for the older patient is an assessment of the patient's decision-making capacity. Among older adults, only about 3% lack medical decision-making capacity. However, among older adults with mild cognitive impairment, this proportion is as high as 20%.[76] A Mini-Cog exam (see section on "Cognition") is an efficient way to screen for cognitive impairment in the surgical setting. If the patient does not have capacity, treatment goals and choices should be discussed with the patient's surrogate, with patient involvement as appropriate. Even cognitively intact patients may have difficulty grasping the risks and tradeoffs involved in decisions for surgery. The "teach-back" method (i.e., asking patients to communicate back information about their diagnosis, treatment plan, and potential risks of treatment) may be useful to confirm that the risks, expected benefits, and alternatives to surgery are fully understood. Various resources are available to aid in using the teach-back method (e.g., http://www.teachbacktraining.org).

Collaborative decision making is essential in older adults with limited life expectancy. Rather than a traditional conversation that focuses on the process of correcting the underlying surgical condition, the conversation should be driven by a focus on the older adult's overarching health goals. Using open-ended questions, physicians elicit the patient's global healthcare goals that may prioritize (1) life prolongation; (2) function and independence; (3) maintenance of cognition; or (4) comfort. Further discussion should be framed by the patient's most important health goal. A frank, realistic, and granular conversation about the ability of surgery to satisfy healthcare goals and priorities is essential. Invasive treatments should only be considered if there is a realistic possibility that overarching health goals can be achieved. These goals, however, are often dynamic and must be revisited as conditions change. Often, primary physicians who have longitudinal relationships with patients can provide important insight into their patient's health goals and should be included in this important deliberation. To assist in high-risk surgical decision making, preoperative palliative care consultation should be considered in individuals with poor prognoses who are electing to undergo surgery, particularly if they have a life expectancy of less than 6 months.

Preoperative Evaluation of Patients With Coexisting Disease

For some conditions commonly seen in the preanesthetic assessment clinic, preoperative optimization, testing, and intervention may be important (see also Chapter 32). Identification of these comorbid conditions might be an opportunity for the anesthesiologist to intervene to decrease perioperative risk. These conditions are best managed before the day of surgery, thus allowing ample time for thoughtful evaluation, consultation, and planning.

CARDIOVASCULAR DISEASE

Cardiovascular complications are serious perioperative adverse events that account for about 45% of all deaths within 30 days after major noncardiac surgery.[77] These events occur relatively frequently. For example, the multicenter Vascular Events in Noncardiac Surgery Patients Cohort Evaluation prospective cohort study found a 4% risk of myocardial infarction, 17% risk of prognostically important myocardial injury, and 0.7% risk of acute heart failure during the 30 days following major noncardiac surgery.[78] Evidence-based preoperative cardiovascular assessment guidelines have now been published in several countries, including the 2014 American College of Cardiology (ACC) and American Heart Association (AHA) guidelines,[7] 2014 European Society of Cardiology (ESC) and ESA guidelines,[9] 2017 Canadian Cardiovascular Society (CCS) guidelines,[8] 2017 Brazilian Society of Cardiology guidelines,[79] and 2014 Japanese Circulation Society guidelines.[80] While the guidelines provide generally similar guidance, there are some important differences that will be highlighted in the sections below.

Hypertension

Based on revised 2017 ACC/AHA guidelines, hypertension is defined as a blood pressure greater than 130/80 based on appropriately measured arterial blood pressure.[81] About 45% of adults in the United States have hypertension,[82] with a similar prevalence in other countries. While most individuals with hypertension have primary (or essential) hypertension, there are several important causes of secondary hypertension, including primary renal disease, OSA, pheochromocytoma, renovascular hypertension, Cushing syndrome, hyperthyroidism, and coarctation of the aorta. Hypertension leads to significantly increased risks of left ventricular hypertrophy (LVH), heart failure, ischemic heart disease, chronic kidney disease (CKD), ischemic stroke, intracerebral hemorrhage, and PAD. The duration and severity of hypertension are highly correlated with subsequent end-organ damage, morbidity, and mortality. These risks appear to increase once blood pressure exceeds 117/75, with each subsequent 20 mm Hg increase in systolic blood pressure and 10 mm Hg increase in diastolic blood pressure being associated with a two-fold increase in the risk of stroke and cardiovascular death.[83] In the perioperative setting, hypertension is associated with increased risks of postoperative death and myocardial infarction, but the magnitude of this association is relatively weak (odds ratio 1.35; 95% confidence limits, 1.17-1.56).[84]

In patients with hypertension, the goals of preoperative evaluation are to identify any secondary causes of hypertension, presence of other cardiovascular risk factors (e.g., smoking, diabetes mellitus), and evidence of end-organ damage. For example, paroxysmal hypertension or hypertension in young individuals should prompt a search for hyperthyroidism, illicit drug use (e.g., cocaine, anabolic steroids), and coarctation of the aorta. Similarly, a history of paroxysmal hypertension associated with episodic tachycardia and palpitations should raise suspicions about an underlying pheochromocytoma (see next section). The physical examination should focus on vital signs (including blood pressure measured in both arms), thyroid gland, peripheral pulses, and cardiovascular system (including bruits and signs of intravascular volume overload). Additional specialized testing is directed by the initial clinical evaluation. For example, patients with long-standing, severe, or poorly controlled hypertension should undergo an ECG and blood sampling to measure creatinine concentration. Individuals on diuretic antihypertensives (e.g., chlorthalidone, hydrochlorothiazide) may require evaluation of electrolytes. Patients with suspected hyperthyroidism will require thyroid function tests.

While preoperative hypertension is associated with an increased risk of cardiovascular complication,[84] this association is generally not evident for systolic blood pressure values less than 180 mm Hg or diastolic blood pressure values less than 110 mm Hg. Additionally, there is no compelling data that delaying surgery to optimize blood pressure control will result in improved outcomes. Accordingly, some international practice guidelines support proceeding with surgery if the systolic blood pressure is less than 180 mm Hg and diastolic blood pressure is less than 110 mm Hg.[9,49] Usual antihypertensive medication treatment should be continued in these patients during the perioperative period. For patients with severe hypertension (i.e., diastolic blood pressure > 110 mm Hg or systolic blood pressure > 180 mm Hg), anesthesiologists should weigh the potential benefits of delaying surgery to optimize antihypertensive treatment against the risks of delaying the procedure. In general, all long-term antihypertensive treatment should be continued up to the day of surgery, with the possible exception of angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs). Administration of these medications within 24 hours before surgery is consistently associated with increased risks of intraoperative hypotension,[85] and possibly associated with elevated risks of postoperative myocardial injury.[86] Accordingly, it is reasonable to withhold these medications for 24 hours before surgery, provided that they are restarted postoperatively once patients are hemodynamically stable. Importantly, failure to resume ACEI and ARB therapy postoperatively is itself associated with adverse outcomes.[87,88]

Even if surgery is not necessarily delayed to facilitate improved blood pressure control, the preanesthesia evaluation should also be viewed as an excellent opportunity to alter long-term consequences of diseases. Thus, appropriate postsurgery referrals should be made to facilitate improved long-term management of hypertension.

Ischemic Heart Disease

Ischemic heart disease (IHD) afflicts about 16.5 million adults in the United States, and 111 million people worldwide.[27] It also accounts for about 13% of all deaths, both in the United States and worldwide (http://www.who.int/mediacentre/factsheets/fs317/en/).[27] While death rates attributable to IHD are declining in many high-income countries,[89] other regions continue to experience high or increasing rates of IHD mortality. IHD mediates adverse effects because of its immediate impact (e.g., myocardial infarction, sudden cardiac death) and related diseases (e.g., heart failure, atrial fibrillation). Therapy for IHD includes antiplatelet therapy (e.g., aspirin, adenosine diphosphate receptor [$P2Y_{12}$] inhibitor), renin angiotensin system inhibitors (e.g., ACEI, ARB), β-adrenergic blockers, other antianginal therapies (e.g., calcium channel blocker, nitrates), lipid reducing agents (e.g., statins), and coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI). Based on recent randomized controlled trials, several newer types of medical therapy for IHD may be increasingly used, including novel antiinflammatory therapy (e.g., canakinumab),[90] low-dose direct oral anticoagulant (DOAC) therapy,[91] and antibody-based lipid-lowering agents.[92] Coronary revascularization—specifically with CABG—improves survival compared to medical therapy (pooled relative risk 0.80, 95% limits 0.70-0.91) in several high-risk IHD states,[93] namely left main coronary artery stenosis, triple-vessel coronary artery disease, and two-vessel coronary artery disease with proximal left anterior descending artery stenosis.[94] When PCI is used instead for these high-risk states, PCI with a newer generation drug eluting stent (DES) may also confer a survival benefit, albeit with marginal statistical significance.[93] In patients who meet indications for revascularization, CABG improves survival more than PCI in multivessel disease that is associated with either diabetes mellitus or higher coronary artery lesion complexity.[95] Notably, aside from these high-risk states (e.g., triple vessel coronary artery disease), PCI has not been shown to convincingly improve survival in stable IHD.[96]

In the perioperative setting, IHD is a risk factor for myocardial infarction and a prognostically important myocardial injury after surgery.[97,98] It is also associated with elevated risks of 30-day postoperative mortality,[99] especially if a patient had experienced a myocardial infarction, acute coronary syndrome, or severe angina (i.e., occurring at effort levels less than walking one to two blocks or climbing one flight of stairs) within the 6 months preceding surgery.[77,78] Surgical patients with IHD may also have important comorbidities with important perioperative implications, such as heart failure and atrial fibrillation (see sections of "Heart Failure" and "Atrial Fibrillation"). The goals of preoperative evaluation are to (1) ascertain whether the patient has previously undiagnosed significant IHD; (2) characterize any known IHD with respect to severity, functional limitations, therapy, and prior investigations; (3) determine whether additional preoperative specialized testing or consultations are warranted; and (4) identity opportunities for reducing perioperative risk related to IHD. In the case of patients without known IHD, evaluation of traditional risk factors for IHD (i.e., smoking, hypertension, increased age, male sex, hyperlipidemia, family history) is important when significance of suspicious symptoms (e.g., chest discomfort, dyspnea) or abnormal ECG. In patients with known IHD, the anesthesiologist should characterize any history of chest discomfort (i.e., pain, pressure, tightness) with respect to its duration, precipitating factors, associated symptoms, and relieving factors. Exertional dyspnea may represent an angina equivalent but is also a nonspecific finding that might be related to physical deconditioning, pulmonary disease, or heart failure. It is useful to classify any angina based on the CCS grading scale:

- CCS class I: Ordinary physical activity (e.g., walking, climbing stairs) does not cause angina. Angina with strenuous or rapid or prolonged exertion at work or recreation
- CCS class II: Slight limitation of ordinary activity. No angina is precipitated by walking more than two blocks on level ground or climbing more than one flight of stairs at a normal pace and in normal conditions. Angina is only precipitated by walking or climbing stairs rapidly, walking uphill, and walking or stair climbing under challenging conditions (e.g., after meals, in cold, in wind, under emotional stress, during the few hours after awakening).
- CCS class III: Marked limitation of ordinary physical activity. Angina precipitated by walking one or two blocks on level ground and climbing one flight of stairs in normal conditions and at normal pace.
- CCS class IV: Inability to carry on any physical activity without discomfort. Angina may be present at rest.

Patients with risk factors for IHD or suspicious symptoms may require an ECG, especially before intermediate-risk or high-risk surgical procedures.[9] Routine preoperative ECGs are not indicated (Box 31.2), especially in asymptomatic patients without known cardiovascular disease or risk factors.[7] While specific preoperative abnormalities are associated with increased perioperative cardiac risk (e.g., bundle branch blocks [BBBs]), these abnormalities do not enable clinicians to identify patients with increased perioperative cardiac risk more accurately when considered in combination with known clinical risk factors.[100] Establishing a baseline for postoperative comparison is often the most important reason to obtain a preoperative ECG; however, this decision should be based on the patient's likely risk of postoperative cardiovascular complications. Thus, a baseline ECG is unlikely to be helpful in an individual at very low risk for postoperative cardiac events. If a previous ECG is available from the previous 3 months and there has been no intervening change in clinical status, a repeat ECG is likely not needed.[7] Other typical preoperative laboratory tests that may be considered for patients with known or suspected IHD include creatinine and hemoglobin concentrations. Both chronic renal insufficiency and anemia are risk factors for perioperative cardiac complications.[97,101,102] In addition, anemia can modify the effects of β-adrenergic blockade in surgical patients, with evidence of increased harm when used in patients with perioperative anemia or significant bleeding.[103,104]

BOX 31.2 Recommendations for Preoperative Resting 12-Lead Electrocardiogram

Class IIa Recommendation: It Is Reasonable to Perform the Procedure

Preoperative resting 12-lead ECG is reasonable for patients with known IHD, significant arrhythmia, PAD, CVD, or other significant structural heart disease (except if undergoing low-risk surgical procedures).

Class IIb Recommendation: The Procedure May Be Considered

Preoperative resting 12-lead ECG may be considered for asymptomatic patients without known coronary heart disease, except for those undergoing low-risk surgical procedures.

Class III Recommendation: The Procedure Should *Not* Be Performed Because It Is Not Helpful

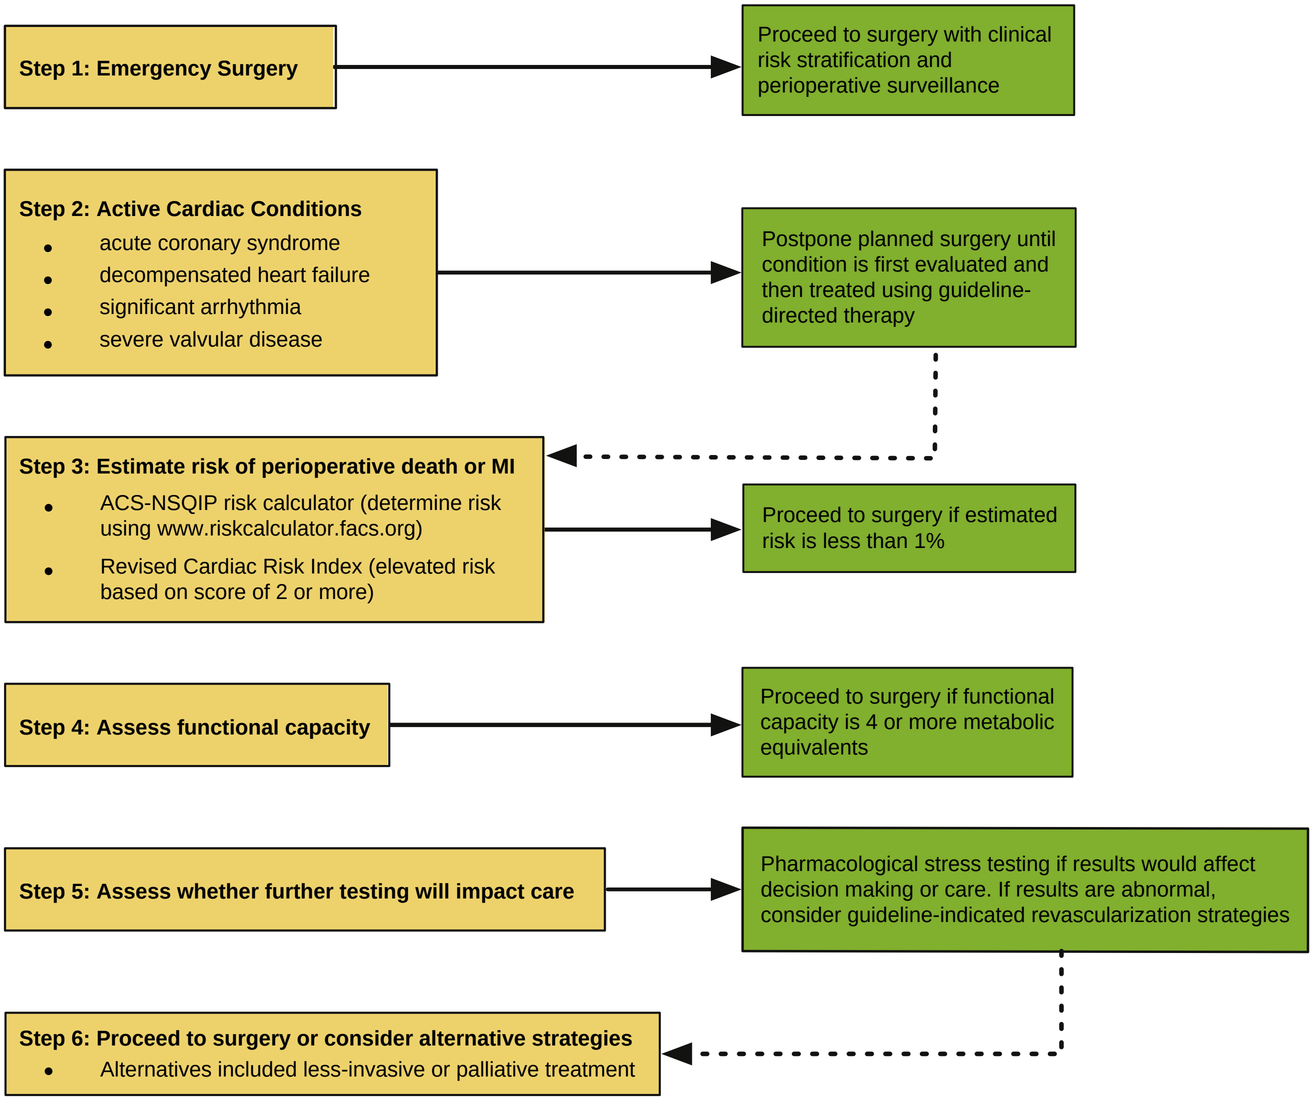
Routine preoperative resting 12-lead ECG is not useful for asymptomatic patients undergoing low-risk surgical procedures.

CVD, Cerebrovascular disease; *ECG,* electrocardiogram; *IHD,* ischemic heart disease; *PAD,* peripheral artery disease.

From Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2014;130:e278–e333.

Preoperative cardiac risk assessment algorithms have been proposed by several practice guidelines, including the ACC/AHA guidelines (Fig. 31.5)[7] and the CCS guidelines (Fig. 31.6).[8] These algorithms have somewhat differing target populations. The ACC/AHA algorithm encompasses patients with known IHD or associated risk factors who are having noncardiac surgery. The CCS guidelines focus on adults (≥18 years old) having inpatient surgery who are either 45 years or older, or who have significant cardiovascular disease (i.e., IHD, cerebrovascular disease [CVD], PAD, heart failure, severe pulmonary hypertension, severe obstructive cardiac valvular disease). While the algorithms have many fundamental similarities, they also have several key differences, which will be discussed below. Importantly, the algorithms should always be viewed as flexible guidance frameworks that should be tailored, as needed, to individual patients. The initial step in these risk assessment algorithms is consideration of the urgency of the planned surgery. The 2014 ACC/AHA guidelines define an *emergency* procedure as one where life or limb would be threatened if surgery did not proceed within 6 hours or less; an *urgent* procedure as one where life or limb would be threatened if surgery did not proceed within 6 to 24 hours; and a *time-sensitive* procedure as one where delays exceeding 1 to 6 weeks would adversely affect outcomes (e.g., most oncology surgery).[7] Based on this classification scheme, patients should proceed directly to any required emergency surgery without further preoperative cardiac assessment.[7,8] For these individuals, the focus should be on surveillance (e.g., serial cardiac enzymes, hemodynamic monitoring, serial ECGs) and early treatment of any postoperative cardiovascular complications.

In the second step, active cardiac conditions—such as acute coronary syndromes, decompensated heart failure, severe valvular disease (e.g., critical aortic stenosis), suspected significant pulmonary hypertension, or significant arrhythmias (e.g., atrial fibrillation with rapid ventricular rate, sustained ventricular tachycardia)—should be ruled



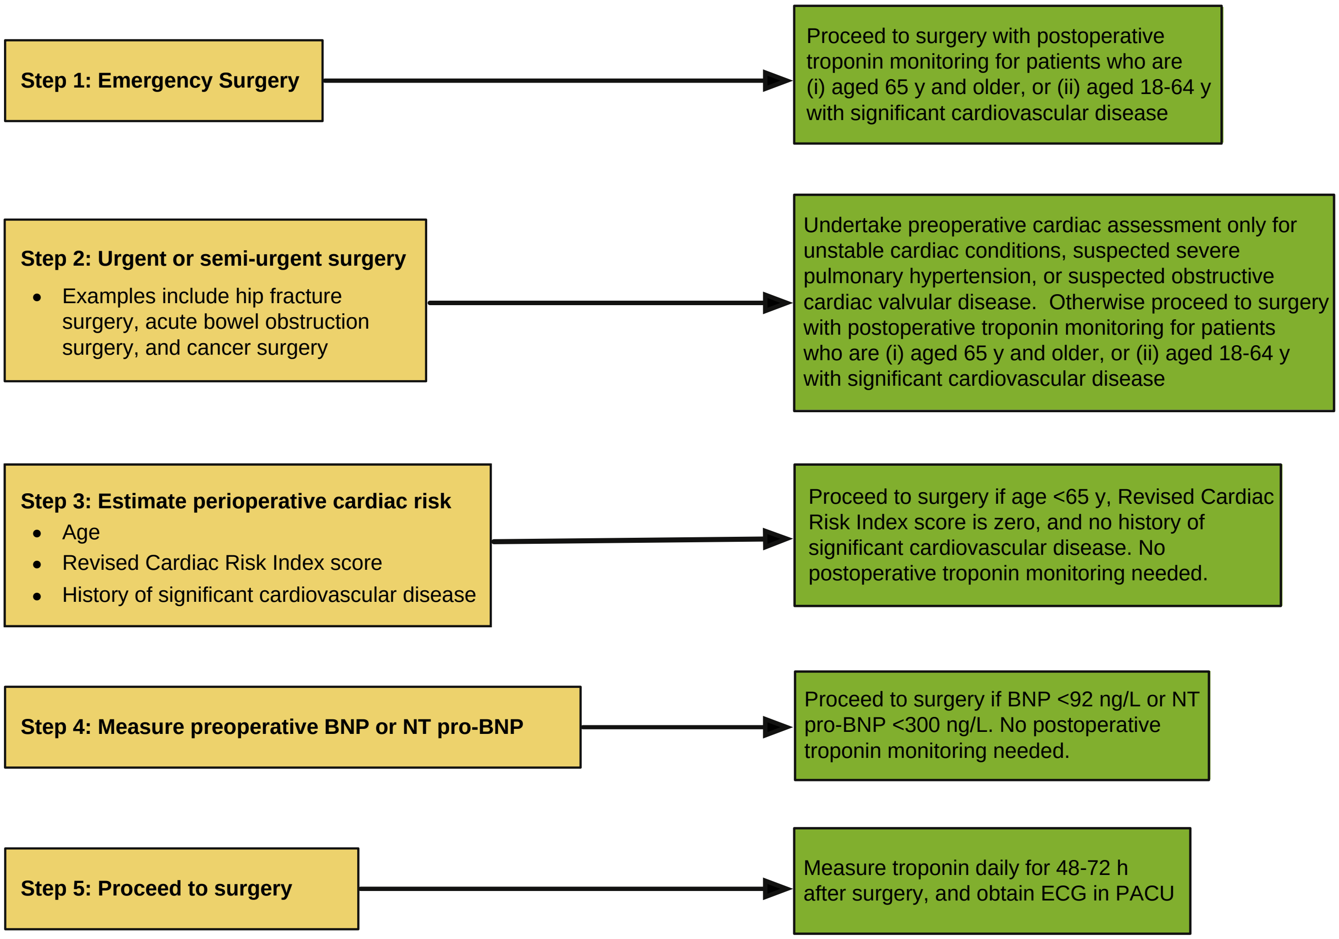
Step 1: Emergency Surgery
Proceed to surgery with clinical risk stratification and perioperative surveillance
Step 2: Active Cardiac Conditions
acute coronary syndrome
decompensated heart failure
significant arrhythmia
severe valvular disease
Postpone planned surgery until condition is first evaluated and then treated using guideline-directed therapy
Step 3: Estimate risk of perioperative death or MI
ACS-NSQIP risk calculator (determine risk using www.riskcalculator.facs.org)
Revised Cardiac Risk Index (elevated risk based on score of 2 or more)
Proceed to surgery if estimated risk is less than 1%
Step 4: Assess functional capacity
Proceed to surgery if functional capacity is 4 or more metabolic equivalents
Step 5: Assess whether further testing will impact care
Pharmacological stress testing if results would affect decision making or care. If results are abnormal, consider guideline-indicated revascularization strategies
Step 6: Proceed to surgery or consider alternative strategies
Alternatives included less-invasive or palliative treatment

Fig. 31.5 Simplified cardiac evaluation algorithm for noncardiac surgery proposed by the 2014 American Heart Association and American College of Cardiology guidelines. *ACS-NSQIP*, American College of Surgeons National Surgical Quality Improvement Program; *MI*, myocardial infarction. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:e278–e333.)

out in patients not requiring emergency surgery.[7] If any of these conditions are present, they must be initially treated, after which the original planned surgery can be reconsidered based on its risk-benefit balance. When assessing whether a patient has an active cardiac condition, the anesthesiologist should inquire about any recent myocardial infarction. In a study of about 560,000 patients who underwent major noncardiac surgery in the United States,[105] the risk of 30-day postoperative myocardial infarction or death was significantly elevated when surgery was performed within 60 days after a prior myocardial infarction. Thus, the 2014 ACC/AHA guidelines recommend deferring nonurgent surgery until 60 days after a recent myocardial infarction.[7]

In the third step, perioperative cardiac risk should be estimated based on readily available clinical information that encompasses both patient-level (e.g., comorbidities) and surgery-level (e.g., procedure type) characteristics. The 2014 ACC/AHA guidelines and 2014 ESC/ESA guidelines recommend using clinical risk indices, namely the Revised Cardiac Risk Index (RCRI) (Table 31.5),[97] ACS NSQIP surgical risk calculator (https://riskcalculator.facs.org/RiskCalculator),[32] or NSQIP Myocardial Infarction and Cardiac Arrest risk calculator.[33] If these indices find the estimated risk of postoperative myocardial infarction or death to be less than 1% (consistent with RCRI ≤ 1), the ACC/AHA guidelines recommend that patients simply proceed directly to surgery.[7] The 2017 CCS guidelines suggest using the RCRI, as opposed to the NSQIP risk calculators, largely because the NSQIP-risk models were developed using a database without routine postoperative troponin surveillance, implying that the predicted absolute myocardial infarction rate might underestimate the true rate by threefold,[98] and have not been externally validated.[8] In addition, the NSQIP risk calculators have largely not been externally validated. By comparison, the RCRI was derived in a cohort study with standardized cardiac biomarker surveillance,[97] and also has undergone extensive external validation.[106] Nonetheless, the RCRI has limitations, especially with respect to inadequate consideration of variations in cardiac risk across different surgical procedures.[107] The CCS guidelines recommend that patients proceed directly to surgery if they meet all the following criteria: age over 65 years, RCRI score of 1 or greater, and no history of significant cardiovascular disease (i.e., coronary artery disease, CVD, PAD, heart failure, pulmonary hypertension, or severe obstructive cardiac valvular disease).

In the fourth and subsequent steps, there are substantial differences between the American versus Canadian preoperative risk assessment algorithms. The ACC/AHA algorithm recommends that a patient with a functional capacity



Step 1: Emergency Surgery
Proceed to surgery with postoperative troponin monitoring for patients who are (i) aged 65 y and older, or (ii) aged 18-64 y with significant cardiovascular disease
Step 2: Urgent or semi-urgent surgery
• Examples include hip fracture surgery, acute bowel obstruction surgery, and cancer surgery
Undertake preoperative cardiac assessment only for unstable cardiac conditions, suspected severe pulmonary hypertension, or suspected obstructive cardiac valvular disease. Otherwise proceed to surgery with postoperative troponin monitoring for patients who are (i) aged 65 y and older, or (ii) aged 18-64 y with significant cardiovascular disease
Step 3: Estimate perioperative cardiac risk
• Age
• Revised Cardiac Risk Index score
• History of significant cardiovascular disease
Proceed to surgery if age <65 y, Revised Cardiac Risk Index score is zero, and no history of significant cardiovascular disease. No postoperative troponin monitoring needed.
Step 4: Measure preoperative BNP or NT pro-BNP
Proceed to surgery if BNP <92 ng/L or NT pro-BNP <300 ng/L. No postoperative troponin monitoring needed.
Step 5: Proceed to surgery
Measure troponin daily for 48-72 h after surgery, and obtain ECG in PACU

Fig. 31.6 Simplified cardiac evaluation algorithm for noncardiac surgery proposed by the 2017 Canadian Cardiovascular Society guidelines. *BNP,* Brain natriuretic peptide; *ECG,* electrocardiogram; *NT pro-BNP,* N-terminal-pro-BNP; *PACU,* postanesthesia care unit. Canadian Cardiovascular Society guidelines on perioperative cardiac risk assessment and management for patients who undergo noncardiac surgery. *Can J Cardiol.* 2017;33:17–32.)

of 4 or more METs should proceed directly to surgery.[7] This guidance is largely based on older studies of preoperative exercise testing,[30,31] and more recent studies of preoperative CPET,[108,109] which found an association between poor functional capacity and elevated perioperative cardiac risk. The major clinical challenge with this recommendation pertains to how best to estimate patients' preoperative functional capacity in clinical practice (see earlier section on "Assessment of Functional Capacity"). Simple subjective assessment of functional capacity based on the usual preoperative history does not accurately estimate true exercise capacity,[36] and does not accurately predict postoperative cardiovascular complications.[36,41] Thus, in clinical practice, anesthesiologists should generally use a structured questionnaire, especially the DASI (see Table 31.2),[42] with consideration of formal exercise testing if the results would alter management. Notably, DASI scores improve the accuracy of prediction of cardiac complications following noncardiac surgery beyond that achieved with the RCRI alone.[36]

TABLE 31.5 Components of the Revised Cardiac Risk Index and Expected Cardiac Event Risk

Components of Revised Cardiac Risk Index*	Points Assigned
High-risk surgery (intraperitoneal, intrathoracic, or suprainguinal vascular procedure)	1
Ischemic heart disease (by any diagnostic criteria)	1
History of congestive heart failure	1
History of cerebrovascular disease	1
Diabetes mellitus requiring insulin	1
Creatinine > 2.0 mg/dL (176 μmol/L)	1
Revised Cardiac Risk Index Score	**Risk of Major Cardiac Events†,‡**
0	0.4%
1	1.0%
2	2.4%
≥3	5.4%

†Data from Devereaux OJ, Goldman L, Cook DJ, et al. Perioperative cardiac events in patients undergoing noncardiac surgery: a review of the magnitude of the problem, the pathophysiology of the events and methods to estimate and communicate risk. *CMAJ*. 2005;173:627–634.

‡Defined as cardiac death, nonfatal myocardial infarction, or nonfatal cardiac arrest.

If a patient is deemed to have either low (i.e., < 4 METs) or uncertain functional capacity, the AHA/ACC guidelines recommend consideration of exercise or pharmacologic cardiac stress testing, if the results could plausibly inform decision making or clinical care. Patients with high-risk abnormal test results can be considered for subsequent coronary angiography, and possibly revascularization (if usual nonoperative indications for coronary revascularization are met). Importantly, the ACC/AHA guidelines emphasize the importance of considering alternative less invasive or nonsurgical treatment for the underlying condition, especially in patients found to be at very high cardiac risk.

As opposed to assessing functional capacity, the CCS guidelines recommend preoperative risk assessment with cardiac biomarkers,[8] specifically brain natriuretic peptide (BNP) or N-terminal-pro-BNP (NT pro-BNP). These neurohormones are secreted by the cardiac ventricles in response to stretch or ischemia of the atrial and ventricular walls. In the nonoperative setting, elevated natriuretic peptide concentrations are powerful markers of cardiovascular risk in individuals with IHD or associated risk factors, as well as in individuals with heart failure.[110] Interestingly, there is only slight-to-fair correlation between plasma levels of these biomarkers and measures of exercise capacity,[36] suggesting that natriuretic peptides measure a different patient characteristic. An individual patient data meta-analysis of 18 studies in noncardiac surgery found that preoperative natriuretic peptide concentrations can differentiate patients based on their perioperative cardiac risk (Table 31.6).[111] In general, BNP concentrations less than 100 ng/L or NT pro-BNP concentrations less than 300 ng/L are indicative of a patient at very low perioperative cardiac risk. Conversely, BNP concentrations above 300 ng/L or NT pro-BNP concentrations above 900 ng/L are indicative of a patient at high cardiac risk. Importantly, natriuretic peptides also improve the accuracy of risk estimation beyond that achieved with traditional clinical risk factors alone.[111] The CCS guidelines recommend that preoperative BNP or NT pro-BNP testing be used to inform the required level of postoperative surveillance. Specifically, they recommend

TABLE 31.6 Risk of Death or Myocardial Infarction After Noncardiac Surgery Based on Preoperative Brain Natriuretic Peptide or N-Terminal-Pro-Brain Natriuretic Peptide Concentrations

Preoperative BNP Concentration (ng/L)	Likelihood Ratio* for Death or MI	Preoperative NT pro-BNP Concentration (ng/L)	Likelihood Ratio* for Death or MI
0–99	0.6	0–300	0.4
100–250	1.4	301–900	1.5
>250	3.9	901–3000	2.7
		>3000	5.0

*Positive test results should have likelihood ratios > 2 to provide clinically meaningful information, whereas negative test results should have likelihood ratios of < 0.5.

BNP, Brain natriuretic peptide; *MI,* myocardial infarction; *NT pro-BNP,* N-terminal-pro-BNP.

B-type natriuretic peptide and N-terminal fragment of pro-B-type natriuretic peptide: a systematic review and individual patient data meta-analysis. *J Am Coll Cardiol.* 2014;63:170–180.

routine troponin surveillance for 48 to 72 hours after surgery in patients with elevated preoperative BNP (≥92 ng/L) or NT pro-BNP (≥300 ng/L) concentrations. No other preoperative testing or intervention is recommended based on the results of preoperative cardiac biomarker testing.

Although current evidence pertaining to risk assessment with preoperative natriuretic peptides is promising, there are also some important limitations. First, the event rate for death or myocardial infarction in this individual patient data meta-analysis was about 11%, which is considerably higher than would be expected in usual clinical practice. This high event rate is explained, in part, by the intermediate-to-high risk characteristics of the study sample, and by two large included studies that defined cardiovascular complications based on elevated troponin concentrations alone (as opposed to less frequent myocardial infarction events).[112,113] Therefore, further research remains needed to determine biomarker threshold levels and prognostic accuracy in generalizable study samples. Second, while elevated natriuretic peptide concentrations are indicative of elevated perioperative cardiac risk, they do not indicate underlying pathophysiological mechanism. Aside from ischemia and heart failure, other prognostically important conditions can cause elevated natriuretic peptide concentrations, including right ventricular dysfunction, cardiac valvular disease, and atrial fibrillation. Thus, further specialized testing (e.g., echocardiography) may be helpful in some patients with high preoperative BNP or NT pro-BNP concentrations, if the results might inform clinical care or decision making. Third, nonoperative data suggest natriuretic peptides have limitations as prognostic biomarkers in certain disease states, including obesity and chronic renal kidney.

The anesthesiologist has several other avenues for further investigating or optimizing known or suspected IHD before surgery—including consultations, biomarkers, stress testing, coronary angiography, coronary revascularization, and medical therapy. When considering the need for additional consultations before surgery, an initial phone call to the primary care physician or cardiologist often yields important information that obviates the need for further consultation. Any specialist consultation (e.g., cardiologist) initiated by the anesthesiologist should seek specific advice regarding the diagnosis, treatment, or further optimization of the patient's condition. It is preferable to ask specific questions, such as "*Does this patient have IHD?*" or "*Is this patient optimized for planned radical nephrectomy?,*" to avoid unhelpful consultation reports that simply state that a patient is "*cleared for surgery.*"

Aside from BNP and NT pro-BNP, several other preoperative biomarkers have shown promise, with the most compelling data pertaining to high-sensitivity troponin assays. In the nonoperative setting, these high-sensitivity assays have demonstrated subtle resting elevations in cardiac troponin concentrations in an important segment of the population without any acute coronary syndrome. These individuals have significantly elevated risks of death, as well as progression to IHD or heart failure.[114,115] Perhaps unsurprisingly, many otherwise stable surgical patients may have elevated troponin concentrations even before surgery. For example, in a cohort study of 325 patients undergoing major inpatient noncardiac surgery, about 20% had a preoperative high-sensitivity troponin T concentration exceeding the 99th percentile for the assay.[116] Thus, especially in patients for whom postoperative troponin surveillance is planned, a preoperative troponin measurement is integral to determining whether any elevated postoperative concentration reflects acute injury versus chronic long-term elevation. Two large cohort studies have also shown that these preoperative troponin elevations may aid in risk stratification for noncardiac surgery.[117-119] Specifically, a preoperative high-sensitivity troponin T concentration above 14 ng/L is associated with increased risks of death and cardiovascular complications after major noncardiac surgery. Furthermore, addition of preoperative high-sensitivity troponin T appears to improve the accuracy of risk estimation beyond that achieved with traditional clinical risk factors and natriuretic peptides.[117,118] Further research remains needed to confirm these initial results, establish ideal screening thresholds, and replicate these analyses using other high-sensitivity troponin assays. Importantly, prognostically important conditions other than myocardial ischemia can cause elevated troponin concentrations, including right ventricular dysfunction, cardiac valvular disease, and atrial fibrillation.

When supplementing preoperative evaluation, cardiac stress testing can help diagnose IHD, assess its severity, and estimate perioperative cardiac risk. The tests therefore address both *diagnosis* and *prognosis*. Several stress tests are available that differ based on the stress modality (i.e., exercise, pharmacologic) and ischemia monitoring method (i.e., ECG, perfusion imaging, echocardiography). An exercise stress test is a preferred option for a patient who is capable of exercising and likely to achieve an adequate heart rate response during exercise. Exercise stress testing also allows for an objective measurement of functional capacity. An adequate test result is obtained when patients can exercise to 85% of their target heart rate (i.e., 220 minus age). Pharmacologic stress modalities (e.g., dobutamine, dipyridamole, adenosine, regadenoson) are indicated for an individual who cannot exercise or is unlikely to achieve an adequate heart rate response because of pacemakers, significant bradycardia, or high-dose negative chronotropic drugs (e.g., β-adrenergic blockers). The choice of pharmacologic stress modality is generally immaterial, but there are some exceptions. For example, since dobutamine uncovers ischemia by increasing contractility, heart rate, and blood pressure, it may not be the best choice in patients with pacemakers, significant bradycardia, aortic aneurysms, cerebral aneurysms, or poorly controlled hypertension. While adenosine and dipyridamole rely on their vasodilatory properties and do not depend on a heart rate response, they may exacerbate bronchospasm in patients taking theophylline. In addition, these drugs may cause dangerous reductions in preload in the presence of severe stenotic valvular heart disease.

An exercise ECG stress test is a reasonable option for a patient with a relatively normal baseline ECG who is capable of exercising with an adequate heart rate response. An imaging monitoring method (i.e., echocardiography, myocardial perfusion imaging) can be used instead if a patient has significant ECG abnormalities (e.g., left bundle branch block [LBBB], LVH with strain pattern) that may interfere with electrocardiographic detection of ischemia. Nonetheless, exercise myocardial perfusion imaging may still be problematic in patients with LBBB, because of false-positive results related to septal perfusion defects.[7] Stress echocardiography assesses for wall motion abnormalities both at rest and under stress conditions (i.e., exercise, dobutamine). Resting abnormalities indicate scar tissue from a prior infarction, while new abnormalities under stress conditions (i.e., inducible wall motion abnormalities) indicate limited blood due to stenotic coronary lesions. Nuclear myocardial perfusion imaging detects ischemia by comparing radioisotope uptake by viable myocardium under resting and stress conditions. Perfusion defects at rest are indicative of a prior infarction. Since normal coronary arteries vasodilate with exercise or specific pharmacologic stressors (i.e., adenosine, dipyridamole), normal myocardium maintains normal radioisotope uptake in stress conditions. By comparison, stenotic vessels are maximally vasodilated at rest, and unable to further vasodilate under stress conditions. Thus, myocardium with flow-limiting lesions has normal radioisotope update at rest, but decreased uptake under stress conditions (i.e., reversible perfusion defects). In general, the choice of test should be informed by patient factors (e.g., ability to exercise) and local expertise in cardiac stress testing.

Cardiac stress tests can also help predict whether patients are likely to experience perioperative cardiac complications. Since these events occur relatively infrequently, the prognostic performance of these tests should not be evaluated based on positive or negative predictive values. It is preferable to use positive likelihood ratio and negative likelihood ratio values, which can be readily calculated using sensitivity and specificity values.

$$\text{Positive likelihood ratio} = \frac{\text{sensitivity}}{1 - \text{specificity}}$$

$$\text{Negative likelihood ratio} = \frac{1 - \text{sensitivity}}{\text{specificity}}$$

There are relatively few data on the prognostic performance of preoperative exercise ECG stress testing. In a meta-analysis of studies in vascular surgery, exercise ECG stress testing had a positive likelihood ratio of 2.4 and negative likelihood ratio of 0.4 for predicting postoperative cardiac death or myocardial infarction.[120] Conversely, ECG stress testing had diminished predictive performance (positive likelihood ratio 1.8 and negative likelihood ratio 0.8) in a cohort study of 200 patients undergoing mixed noncardiac surgery.[30] Considerably more research has been published pertaining to the prognostic accuracy of preoperative stress testing based on myocardial perfusion imaging or echocardiography. In a meta-analysis in noncardiac surgery, stress echocardiography has a positive likelihood ratio of 4.1 and a negative likelihood ratio of 0.2 for predicting postoperative death or myocardial infarction. In the case of myocardial perfusion imaging, the positive likelihood ratio was 1.8 and negative likelihood ratio was 0.4.[121] The prognostic value of myocardial perfusion imaging might be further improved by considering the extent of reversible defects. In another meta-analysis in vascular surgery, reversible defects on preoperative myocardial perfusion imaging were associated with significantly increased cardiac risk only when the extent of reversibility exceeded 20% of the myocardium.[122] Notably, isolated fixed defects (i.e., no associated reversible defects) were not associated with elevated cardiac risk.[122] While available evidence does suggest that stress echocardiography has better prognostic accuracy, these data should be interpreted cautiously since they are older, heterogeneous, and do not account for varying local expertise in stress testing modalities. In addition, it remains unclear as to whether cardiac stress tests provide *incremental* prognostic information in patients who have already been assessed using clinical risk factors.

Some patients with high-risk findings on initial cardiac stress testing may require subsequent evaluation of coronary anatomy using either noninvasive computed tomography coronary angiography (CTCA) or invasive coronary angiography. These tests can diagnose IHD, assess its severity, and help assess perioperative cardiac risk. Using contemporary imaging technology, CTCA has reasonably high accuracy for detecting clinically significant coronary artery stenosis.[123,124] An initial retrospective cohort study found CTCA to improve prediction of cardiac complications after intermediate-risk noncardiac surgery, as compared to using the RCRI alone.[125] Conversely, a larger multicenter prospective cohort study found that the addition of CTCA to the RCRI was five times more likely to overestimate risk in low-risk individuals than correctly identify a previously misclassified high-risk individual.[126] Thus, CTCA does not appear to be an appropriate first-line test to supplement clinical risk stratification. Nonetheless, it may be a reasonable follow-up option in patients with high-risk cardiac stress test results.

Invasive coronary angiography is the gold standard for diagnosing IHD and may also be a follow-up option for patients with high-risk cardiac stress test results. Two Italian randomized trials in vascular surgery patients have suggested that routine preoperative invasive coronary angiography—followed by revascularization of any critical stenosis—reduces risks of postoperative myocardial ischemia,[127] and long-term mortality.[128,129] Although interesting, these findings still do not support a clinical shift to this invasive assessment strategy, largely because any patient-relevant benefits were seen over long-term follow-up, not the immediate postoperative period. Any merit for an invasive coronary artery assessment strategy is highly related to whether coronary revascularization before noncardiac surgery is beneficial. This issue remains controversial. The most relevant study is the Coronary Artery Revascularization Prophylaxis trial.[130] In the multicenter randomized controlled trial of 510 vascular surgery patients with known significant IHD, preoperative revascularization using CABG or PCI with bare metal stents (BMSs) did not reduce the risk of postoperative myocardial infarction or long-term mortality. Notably, the trial excluded patients with left main coronary artery stenosis, which is the only subgroup where revascularization was associated with improved survival in a related cohort study.[131] At present, both American and European guidelines only recommend consideration for revascularization in patients who meet usual nonoperative indications (e.g., left main coronary artery stenosis, triple-vessel coronary artery disease),[7,9] while the CCS guidelines recommend against preoperative revascularization in any patient with stable IHD.[8]

In general, randomized controlled trials have also *not* shown benefit from de novo medical therapy to decrease perioperative cardiac risk, including β-adrenergic blockers,[132,133] α_2-adrenergic agonists,[134,135] and low-dose aspirin.[136] Despite initial promising data on perioperative β-adrenergic blockade,[137] these benefits were not replicated in larger multicenter randomized trials, such as the Perioperative Ischemic Evaluation Study-1 (POISE-1) trial. Current randomized trial evidence shows that perioperative β-adrenergic blockade reduces the risk of postoperative myocardial infarction, but at the cost of increased risks of acute stroke, hypotension, and death.[133] Although it is possible that these risks are mitigated by starting β-adrenergic blockers several days before surgery,[138,139] and titrating therapy to a reasonable target heart rate without precipitating hypotension, there are no compelling data showing the efficacy and safety of this approach.[140] Caution should especially be exercised when using β-adrenergic blockers in individuals with known CVD because of the risks of perioperative stroke.[132,133]

Conversely, most *long-term* cardiovascular medications in patients with IHD should be continued up to surgery, including β-adrenergic blockers, statins, and most other antihypertensive medications. Nonetheless, there are some exceptions. Since ACEI and ARB administration within 24 hours before surgery is associated with increased risks of hypotension[85] and myocardial injury,[86] it is reasonable to withhold these medications for 24 hours before surgery, provided that they are restarted postoperatively (see section on "Hypertension").[87,88] Despite theoretical benefits,[141] randomized controlled trials to date have not shown benefits from routinely continuing aspirin before noncardiac surgery. For example, in the POISE-2 trial, continuing low-dose aspirin (100 mg/day) did not prevent cardiac complications but increased risks of major bleeding.[136] The lack of clear benefit may be explained, in part, by acute thrombosis being a relatively infrequent contributor to perioperative myocardial infarction.[142,143] Nonetheless, since only one third of participants in the POISE-2 trial had diagnosed vascular disease, it is possible that continuation of aspirin benefits some very high-risk subgroups. Consistent with this possibility, a relatively small post-hoc subgroup analysis from the POISE-2 trial found that perioperative aspirin reduced the risk of death or myocardial infarction in patients with prior PCI.[144] Based on these data, a reasonable strategy is to only continue aspirin *selectively* in patients where the risk of cardiac events is felt to exceed the risk of major bleeding. Other medications that should generally be withdrawn before surgery include $P2Y_{12}$ inhibitors (e.g., clopidogrel, ticagrelor, prasugrel) and DOACs (see sections on "Atrial Fibrillation" and "Preoperative Antiplatelet Therapy").

Coronary Stents

Following PCI with stent implantation, patients require an initial period of dual antiplatelet therapy (DAPT) with aspirin and a $P2Y_{12}$ inhibitor (e.g., clopidogrel, ticagrelor, prasugrel), after which they can be transitioned to aspirin monotherapy. The purpose of DAPT is to prevent potentially catastrophic stent thrombosis during the vulnerable period preceding stent reendothelialization. Temporary preoperative discontinuation of DAPT during this vulnerable period predisposes patients to cardiovascular complications, especially given the prothrombotic state triggered by surgical stress. Based on emerging evidence and improved DES technology, recommendations pertaining to minimum duration of DAPT before elective noncardiac surgery continue to evolve—as reflected in updated 2016 guidelines published by the ACC/AHA.[145] These guidelines recommend that elective noncardiac surgery should be delayed for 30 days or more after BMS implantation. In the case of DES, the ideal recommended minimum delay is 6 months, which is consistent with several cohort studies showing relatively low perioperative cardiac risk when elective noncardiac surgery was performed 6 months or more after DES implantation.[146,147] Based on expert opinion, the guidelines also indicate that elective noncardiac surgery can sometimes be performed from 3 to 6 months after DES implantation (particularly with new generation stents), if the risk of stent thrombosis is judged to be less than the risk of further delaying surgery.[145] When DAPT is temporarily interrupted before noncardiac surgery, the guidelines strongly recommend that aspirin be continued, and $P2Y_{12}$ inhibitor therapy be restarted as soon as possible after surgery.[145]

Although not explicitly indicated in the 2016 ACC/AHA guidelines, factors other than stent type and time interval since PCI should also inform judgments on the safety of performing elective noncardiac surgery in patients with coronary stents. For example, a large retrospective cohort study of about 26,600 patients found that the risks of noncardiac surgery early after stent implantation were increased when PCI had been performed for acute myocardial infarction, as opposed to unstable angina or non-acute coronary syndrome indications.[148] As a consequence, it may be particularly important to delay noncardiac surgery for 6 months when the indication for DES was treatment of an acute myocardial infarction.

During preoperative evaluation, the anesthesiologist should determine the presence, type (drug-eluting vs. bare-metal), location, and original indication of any coronary stent. Given the complex issues related to these patients, subsequent management should be performed in collaboration with a cardiologist and the responsible surgeon, especially for patients receiving DAPT.[145] Whenever possible, surgical procedures should be performed following critical time windows (i.e., 30 days after BMS, or 3-6 months after DES), aspirin should be continued throughout the perioperative period, and any $P2Y_{12}$ inhibitor therapy should be restarted as soon as possible after surgery. The importance of continuing aspirin perioperatively is supported by the substudy of the POISE-2 randomized trial.[144] In this subgroup analysis of 470 patients with prior PCI, aspirin reduced the risk of death or myocardial infarction (hazard ratio, 0.50; 95% confidence limits, 0.26-0.95) without any significantly increased bleeding risk. Unfractionated heparin and low-molecular-weight heparin (LMWH) should not be used to "bridge" patients who have been withdrawn from antiplatelet therapy, especially since heparin can paradoxically increase platelet aggregation.[149] Following surgery, close monitoring for myocardial injury (i.e., serial troponin measurement) should be strongly considered, with any suspected stent thrombosis treated using PCI. High-risk patients are thus ideally best managed in facilities with immediate access to interventional cardiology.

Heart Failure

Heart failure has been defined as a clinical syndrome resulting from impaired diastolic filling or systolic ejection of the cardiac ventricles.[150] Its major clinical manifestations are dyspnea, fatigue, and fluid retention. Although prevalence estimates are affected by differences in diagnostic criteria, recent estimates suggest that heart failure afflicts more than 6.5 million individuals in the United States,[27] and more than 23 million worldwide.[151] Heart failure is the sequelae of a broad array of underlying pathology, including ischemic heart disease (i.e., ischemic cardiomyopathy), hypertension, valvular heart disease, myocarditis, infiltrative disorder (e.g., sarcoidosis, amyloidosis), and peripartum cardiomyopathy. In addition, many affected individuals have no identifiable underlying cause (i.e., idiopathic dilated cardiomyopathy). Several approaches can be used to classify heart failure, including the presence versus absence of associated signs or symptoms (i.e., compensated vs. decompensated heart failure), and the extent of functional limitation. In heart failure patients, functional status is typically classified based on New York Heart Association (NYHA) categories:

- NYHA class I: no limitation of physical activity; ordinary activity not a cause of fatigue, palpitations, or syncope
- NYHA class II: slight limitation of physical activity; ordinary activity resulting in fatigue, palpitations, or syncope
- NYHA class III: marked limitation of physical activity; less than ordinary activity resulting in fatigue, palpitations, or syncope; comfort at rest
- NYHA class IV: inability to do any physical activity without discomfort; symptoms at rest

Heart failure can also be classified based on the severity of ventricular systolic dysfunction, namely as heart failure with reduced ejection fraction (HFrEF) versus heart failure with preserved ejection fraction (HFpEF).[152] Individuals with HFpEF (or diastolic heart failure) have normal left ventricular ejection fraction (≥50%), normal left ventricular end-diastolic volume, and abnormal diastolic function. By comparison, HFrEF (or systolic heart failure) is characterized by more significant left ventricular systolic dysfunction (i.e., ejection fraction ≤ 40%). Individuals with borderline left ventricular systolic function (i.e., ejection fraction 41%-49%) are classified as borderline HFpEF. They tend to have characteristics and outcomes similar to patients with HFpEF.[152] Among patients with heart failure, about half have HFpEF.[153] Although they have a high mortality risk (10%-20% at 1-year),[154,155] patients with HFpEF have lower adjusted risks of death (adjusted hazard ratio 0.68) over long-term follow-up than patients with HFrEF.[155] Most medical therapy for improving morbidity and mortality in heart failure (i.e., ACEI, ARB, aldosterone antagonist, β-adrenergic blocker, ivabradine) has only demonstrated efficacy in HFrEF.[156] In contrast, medical therapy for HFpEF is largely aimed at symptoms and underlying conditions (e.g., hypertension). Other heart failure-related treatments include diuretics (for volume overload), anticoagulants (for atrial fibrillation or left ventricular thrombus), implantable cardioverter-defibrillators (ICDs), or cardiac resynchronization therapy (CRT).

In the perioperative setting, heart failure is a recognized risk factor for mortality and morbidity after major surgery. *Symptomatic* heart failure has been consistently identified as a risk factor for adverse perioperative outcomes in multiple studies. For example, in a retrospective cohort study of about 159,000 Medicare beneficiaries in the United States, heart failure was associated with significantly higher risks of 30-day mortality (adjusted hazard ratio 1.63) after noncardiac surgery.[157] Similarly, a more recent matched cohort study using the NSQIP registry showed new or worsened heart failure within 30 days before surgery to be associated with increased risks of 30-day mortality (adjusted relative risk 2.08) or major morbidity (adjusted relative risk 1.54).[158] Symptomatic heart failure is also a component of the Revised Cardiac Index, which is commonly used for estimating perioperative cardiac risk cardiovascular complications. Among patients with heart failure, perioperative risk may be higher in patients with HFrEF versus HFpEF. Specifically, in a cohort study of 174 heart failure patients undergoing noncardiac surgery, an ejection fraction less than 30% was associated with much higher adjusted risks (adjusted odds ratio 4.88) of postoperative death, myocardial infarction, or heart failure exacerbation.[159] Nonetheless, HFpEF may still be prognostically important in the perioperative setting, as evidenced by a meta-analysis that found diastolic dysfunction to be associated with a doubling (pooled adjusted odds ratio 2.03) in the risk of postoperative adverse cardiac events.[160] Although symptomatic HF is a clear indicator of increased perioperative risk, the prognostic importance of *asymptomatic* systolic dysfunction is less clear. For example, in a cohort study of 339 individuals undergoing noncardiac surgery, a reduced ejection fraction was associated with increased cardiac morbidity, but this information did not improve risk prediction beyond that achieved with clinical risk factors.[161] Similarly, in another cohort study of 570 individuals undergoing noncardiac surgery, a reduced ejection only had prognostic importance within the subgroup with RCRI scores of 2 or greater.[162] Consistent with these data, the current ACC/AHA guidelines discourage routine preoperative assessment of ventricular function (Box 31.3).[7]

The clinical stability of heart failure symptoms prior to surgery is another important determinant of perioperative risk, as evidenced by a single-center retrospective cohort study from the United States.[163] After examination at a hospitalist-run preoperative evaluation clinic, clinically stable heart failure patients had relatively low risks of 30-day mortality (1.3%) after noncardiac surgery, albeit with longer hospital length of stay and higher readmission rates relative to matched controls. Consistent with these data, the ESC/ESA guidelines recommend that elective intermediate-risk and high-risk noncardiac procedures be deferred for at least 3 months after initiation of medical therapy in patients with newly diagnosed heart failure.[9]

The preoperative history pertaining to heart failure should clarify its type, etiology, severity, stability (including prior exacerbations), recent investigations (e.g., echocardiograms), and current therapy (medical and device-based). The anesthesiologist should inquire about recent weight gain, fatigue, shortness of breath, orthopnea, paroxysmal nocturnal dyspnea, nocturnal cough, peripheral edema, hospitalizations, and recent changes in medical management. The patient's functional status should be classified according to the NYHA categories. It is especially important to determine if the signs and symptoms of heart failure are

BOX 31.3 Recommendations for Preoperative Noninvasive Evaluation of Left Ventricular Function

Class IIa (Reasonable to Perform)

- It is reasonable for patients with dyspnea of unknown origin to undergo preoperative evaluation of LV function.
- It is reasonable for patients with heart failure with worsening dyspnea or other change in clinical status to undergo preoperative evaluation of LV function.

Class IIb (May Be Considered)

- Reassessment of LV function in clinically stable patients with previously documented LV dysfunction may be considered if there has been no assessment within a year.

Class III (Should Not Be Performed Since It Is Not Helpful)

- Routine preoperative evaluation of LV function is not recommended.

LV, Left ventricle.

From Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2014;130:e278–e333.

in their usual stable state (i.e., compensated heart failure) or have recently significantly worsened (i.e., decompensated heart failure). Decompensated heart failure is a very high-risk condition that warrants postponement of surgery for all except lifesaving emergency procedures.[7] No consensus exists on how long nonemergent surgery should be deferred after resolution of acute decompensated heart failure, although a reasonable approach is to delay elective procedures (including most time-sensitive procedures) for 1 month, and urgent procedures for 24 hours.

On physical examination, the findings of heart failure may be subtle. Furthermore, they can vary between HFrEF versus HFpEF, and between compensated versus decompensated states. More useful signs for determining heart failure include a third heart sound, jugular venous distension, pulmonary rales, and lower extremity edema.[26] A chest radiograph may provide further diagnostic guidance, especially in dyspneic patients, with pulmonary vascular redistribution and interstitial edema useful findings for supporting the presence of heart failure.[26] Natriuretic peptide measurement can further clarify whether a patient has heart failure. Both BNP and NT pro-BNP have excellent diagnostic performance, especially for ruling out heart failure, in the ambulatory setting (pooled negative likelihood ratio values 0.29-0.38 at manufacturers' recommended thresholds)[164] and emergency department setting (pooled negative likelihood ratio values 0.08-0.13 at manufacturers' recommended thresholds).[165] Preoperative natriuretic peptide concentrations also provide other potentially important information. Both BNP and NT pro-BNP concentrations are markers of perioperative cardiac risk (see section on "Ischemic Heart Disease"). In addition, for heart failure patients who have undergone prior natriuretic peptide measurement, preoperative BNP or NT pro-BNP testing provides insights into whether patients remained in their usual stable clinical state. Consistent with these data, the ESC/ESA guidelines recommend preoperative natriuretic peptide measurement in patients who have established or suspected heart failure, and are undergoing noncardiac intermediate or high-risk noncardiac surgery.[9] While routine preoperative echocardiography (or other noninvasive ventricular function measurement) is not useful, such specialized testing is helpful for assessment of dyspnea of unknown origin or recent altered clinical status in an individual with known heart failure. Furthermore, both American and European guidelines are supportive of selective preoperative echocardiography in clinically stable patients with known ventricular dysfunction,[9] especially in the absence of testing in the previous year (see Box 31.3).[7] Other tests for patients with heart failure include ECGs and blood sampling to measure electrolyte and creatinine concentration. Digoxin levels are not routinely determined unless toxicity, undertreatment, or noncompliance is suspected.

Consideration should be given for collaborative perioperative management with a cardiologist or heart failure specialist of severely affected heart failure patients (i.e., NYHA III or IV; decompensated heart failure) who will undergo intermediate-risk or high-risk procedures. Most medical therapy, including β-adrenergic blockers, hydralazine, nitrates, and digoxin, should be continued preoperatively. Loop diuretics (e.g., furosemide) can be continued on the day of surgery for most procedures since this strategy does not increase risks of intraoperative hypotension or adverse cardiac events.[166] The exception is lengthy high-risk procedures with projected significant blood loss or fluid requirements, in which potent diuretics should be held on the morning of surgery. Since ACEI and ARB administration within 24 hours before surgery is associated with increased risks of intraoperative hypotension,[85] and postoperative myocardial injury,[86] it is reasonable to withhold these medications for 24 hours before surgery, provided that they are restarted postoperatively once patients are hemodynamically stable (see section on "Hypertension").[87,88] Patients on anticoagulant therapy will likely need these medications temporarily discontinued before surgery (see later section on "Atrial Fibrillation"). In addition, patients with pacemakers, ICDs, and CRT devices have their own special perioperative considerations (see later section on "Cardiovascular Implantable Electronic Devices").

Murmurs and Valvular Abnormalities

When a cardiac murmur is identified during preoperative assessment, the subsequent goals are to identify any associated cardiovascular symptoms (e.g., dyspnea, chest discomfort, orthopnea, fatigue, syncope), determine the underlying cause of the murmur, and distinguish clinically significant murmurs from unimportant ones. For example, benign functional murmurs occur with turbulent flow across the aortic or pulmonic outflow tracts during high-flow states such as hyperthyroidism, pregnancy, or anemia. Murmurs can be graded according to loudness (Table 31.7), however, the loudness of a murmur does not necessarily indicate the severity of a lesion. In contrast, the location of the murmur, and changes in intensity associated with maneuvers can be informative (Table 31.8). A Valsalva maneuver decreases right- and left-heart filling, thereby reducing the intensity of most murmurs except those of mitral valve prolapse and hypertrophic cardiomyopathy. Standing also decreases preload, and thereby increases the intensity of murmurs of mitral valve prolapse and hypertrophic cardiomyopathy. Conversely, squatting increases venous return and afterload, thereby increasing most murmurs except those of mitral valve prolapse and hypertrophic cardiomyopathy. Having the patient repeatedly perform a hand grip increases heart rate and arterial blood pressure, thereby augmenting murmurs of mitral regurgitation and aortic insufficiency; conversely, this maneuver decreases murmurs of aortic stenosis and hypertrophic cardiomyopathy. The likelihood of a murmur being pathologic increases in the presence of increased age, cardiovascular risk factors, other abnormal heart sounds, cardiomegaly, abnormal ECG, evidence of excessive intravascular volume, and a history of rheumatic fever, pulmonary disease, or anorectic drug use. Diastolic or continuous murmurs are almost always pathologic and require further evaluation. Nonetheless, it is typically not easy to distinguish benign from pathologic murmurs based on history and physical examination alone. Thus, cardiovascular medicine guidelines now recommend transthoracic echocardiography for the initial evaluation of any patient with suspected valvular heart disease.[167] Additionally, perioperative guidelines recommend preoperative echocardiography for any patient who has clinically suspected moderate or severe valvular stenosis or regurgitation, and no echocardiogram within the previous year.[7,9] For patients with known valvular heart disease, repeat echocardiography is recommended if there has been a significant change in clinical status or physical examination since the last test.

TABLE 31.7 Grading the Intensity of Cardiac Murmurs

Grade	Description
I	Faintest that can be heard with difficulty
II	Faint but easily heard
III	Moderately loud without a thrill
IV	Loud with a palpable thrill
V	Very loud but still need stethoscope (thrill present)
VI	Heard without a stethoscope

Aortic Stenosis. Aortic valve stenosis is the leading cause of left ventricular outflow obstruction in adults. In high-income countries, aortic stenosis principally occurs because of the progressive calcific disease of a native trileaflet valve or a congenitally bicuspid valve. Stenosis of bicuspid valves typically occurs when individuals are in their fourth and fifth decades of life, whereas stenosis of native trileaflet valves occurs once individuals are age 60 years old or older. Aortic stenosis severity is classified based on the valve area and mean transvalvular pressure gradient (Table 31.9). A limitation of using the pressure gradient alone to assess severity is that the gradient may decrease if the left ventricle systolic function begins to decrease. In patients with known aortic stenosis, serial echocardiography is recommended every 6 to 12 months for patients with severe disease, every 1 to 2 years for moderate disease, and every 3 to 5 years for mild disease. After a prolonged asymptomatic phase, symptoms may develop in affected patients once stenosis becomes severe. The cardinal symptoms of severe aortic stenosis are angina, heart failure, and syncope, but patients are much more likely to complain of exertional dyspnea and decreased exercise tolerance.

Aortic stenosis causes a systolic ejection murmur (see Table 31.8), best heard in the right upper sternal border and often radiating to the neck. A similar murmur occurs with aortic *sclerosis*, which is defined as thickening of the aortic valve without associated stenosis. Aortic sclerosis is present in 25% of individuals age 65 years or older, and 50% of individuals age 80 years or older. Aortic sclerosis is associated with an increased risk of cardiovascular events, and a 2% annual risk of progression to aortic stenosis.[168] The radiating pattern of the systolic ejection murmur can help rule out aortic stenosis, with the absence of radiation to the right clavicle being associated with a negative likelihood ratio of 0.1 for aortic stenosis.[169] In addition to a systolic ejection murmur, aortic stenosis is associated with a delayed carotid upstroke and paradoxically split second heart sound. Any patient with a previously undiagnosed suspicious systolic murmur should have an echocardiogram, especially since noncardiologists have difficulty in distinguishing murmurs of aortic stenosis from those of aortic sclerosis. Typical ECG abnormalities associated with aortic stenosis include LVH (often with a strain pattern), left axis deviation, and LBBB.

TABLE 31.8 Descriptions of Murmurs Associated With Cardiac Abnormalities

Lesion	Location	Timing	Description
Aortic Stenosis	Second parasternal interspace	Midsystolic	Crescendo-decrescendo, radiates to the carotids; with or without S_3, S_4; Valsalva maneuver and sustained hand grip exercise decrease intensity
Aortic Insufficiency	Third and fourth parasternal interspaces	Holodiastolic	Decrescendo, blowing, high pitched, radiates to the carotids; Austin-Flint rumble at the apex; squatting, hand grip exercise, and leaning forward increase intensity
Mitral Stenosis	Apex	Middiastolic	Opening snap; low-pitched rumble radiates to the axilla; squatting and hand grip exercise increase intensity
Mitral Regurgitation	Apex	Holosystolic	High pitched, blowing, radiates to the axilla; loud $S_{3;}$ standing decreases intensity; squatting and hand grip exercise increase intensity
Mitral Valve Prolapse	Apex	Late systolic	Crescendo, midsystolic click; Valsalva maneuver and standing increase intensity; squatting decreases intensity
Hypertrophic Cardiomyopathy	Apex, lower left sternal border	Midsystolic	S_4, Single S_2; Valsalva maneuver and standing increase intensity; squatting, passive leg raising, and hand grip exercise decrease intensity

Moderate to severe aortic stenosis is associated with increased risk of perioperative cardiovascular complications.[170,171] Nonetheless, contemporary studies suggest that noncardiac surgery can be performed with acceptable mortality risks in individuals with asymptomatic severe aortic stenosis[171] Thus, guidelines support proceeding with major elective noncardiac surgery in patients with asymptomatic severe aortic stenosis, provided that appropriate intraoperative and postoperative hemodynamic monitoring is available.[7,9] Conversely, for patients with symptomatic severe aortic stenosis, aortic valve replacement should be considered before their planned noncardiac surgery.[7,9] If a symptomatic patient is deemed high-risk or ineligible for surgical aortic valve replacement, alternative intervention options include transcatheter aortic valve replacement (TAVR) or percutaneous aortic balloon dilation.[7,9] Multidisciplinary collaboration with a cardiologist is invaluable for the perioperative management of these high-risk patients.

Patients with moderate to severe aortic stenosis also have an increased risk of bleeding from an *acquired* von Willebrand syndrome, which occurs in 67% to 92% of patients with severe stenosis.[172] The underlying pathophysiology is mechanical disruption of von Willebrand multimers during turbulent blood flow through the narrowed valve. Of note, prophylaxis for infective endocarditis is not recommended.[173]

Aortic Insufficiency. Aortic valve insufficiency occurs with valvular leaflet disease, aortic root dilation, or both. Causes of valvular disease include rheumatic heart disease, bicuspid valves, collagen vascular disease, and endocarditis. With respect to aortic root dilation, causes include ankylosing spondylitis, osteogenesis imperfecta, syphilis, hypertension, age-related degeneration, Marfan syndrome, and collagen vascular diseases. These causes generally lead to progressive chronic aortic insufficiency that remains asymptomatic for decades. In contrast, acute aortic insufficiency can result from trauma, infections, or aortic dissection; this is an emergent condition that results in cardiogenic shock.

On auscultation, aortic insufficiency is associated with a diastolic murmur (see Table 31.8), the intensity of which does not correlate well with the severity of regurgitation.[174] Patients typically have a widened pulse pressure, which manifests as Corrigan or water-hammer pulses (bounding carotid pulse with a rapid downstroke), de Musset sign (head bob with each heart beat), Duroziez sign (systolic and diastolic bruit heard over the femoral artery when it is partially compressed), and Quincke pulses (capillary pulsations in the fingertips or lips). Although auscultation by a cardiologist can help rule in or rule out aortic regurgitation (based on the presence or absence of an early diastolic murmur),[175] the accuracy of auscultation by noncardiologists is uncertain.[26] Thus, an echocardiogram is helpful for any patient suspected of having a diastolic murmur.

TABLE 31.9 Grading Severity of Aortic Stenosis

Grade	Transvalvular Jet Velocity (m/s)	Mean Pressure Gradient (mm Hg)	Valve Area (cm^2)
Mild	2.0–2.9	<20	≥1.5
Moderate	3–3.9	20–39	1.0–1.5
Severe	≥4	≥40	<1.0

Limited prior research suggests that patients with moderate-to-severe aortic insufficiency experience increased risks of perioperative mortality and morbidity, especially in the presence of impaired left ventricular function (ejection fraction < 55%) or renal insufficiency.[176] Nonetheless, expert consensus from current guidelines is supportive of patients with asymptomatic severe aortic insufficiency to proceed with major noncardiac surgery accompanied by careful perioperative management, including hemodynamic monitoring, afterload control, and fluid balance.[7,9,167] Prophylaxis for infective endocarditis is not recommended.[173]

Mitral Stenosis. Mitral stenosis is much rarer than aortic stenosis, and almost always related to rheumatic heart disease. Other less common causes include mitral annular calcification and radiation-associated valve disease. The normal mitral valve has a cross-sectional area of 4 to 6 cm^2. Mitral stenosis involves progressive reduction of this area, with shortness of breath with exertion occurring when the area falls below 2.5 cm^2, and symptoms at rest occurring once the area falls below 1.5 cm^2. Severe mitral stenosis is defined by a valve area less than 1 cm^2 and is typically associated with a pulmonary artery systolic pressure > 50 mm Hg, and a resting mean transvalvular gradient ≥ 10 mm Hg.

When mitral stenosis becomes symptomatic, patients experience dyspnea, fatigue, orthopnea, pulmonary edema, and hemoptysis because of increased left atrial pressures and decreased cardiac output. Atrial fibrillation can also develop, in turn causing heart failure in the short term and thrombosis in the long term. Patients with atrial fibrillation require long-term anticoagulation, with recent guidelines recommending vitamin K antagonist therapy (e.g., warfarin) as opposed to DOACs.[173] Pulmonary hypertension (see later section on “Pulmonary Hypertension”) and right-sided heart failure can also occur in patients with significant stenosis. The physical examination should evaluate for rales and signs of right-sided heart failure such as jugular venous distention, peripheral edema, hepatomegaly, right ventricular heave, and ascites. On auscultation, mitral stenosis is associated with a diastolic murmur that should be evaluated with echocardiography.

Medical management includes β-adrenergic blockers for controlling heart rate, antiarrhythmic agents for preventing or controlling atrial fibrillation, and anticoagulants in patients with atrial fibrillation. Both β-adrenergic blockers and antiarrhythmic agents should be continued preoperatively, while anticoagulation should be managed in conjunction with the treating cardiologist and surgeon. Prophylaxis for infective endocarditis is not recommended.[173] If a patient with mitral stenosis meets guideline-based indications for valvular intervention (e.g., percutaneous mitral balloon commissurotomy),[167] consideration should be given to performing this intervention before major elective noncardiac surgery.[7,9] If an asymptomatic patient with severe mitral stenosis has valve morphology that is not favorable for a percutaneous intervention, it is still reasonable to proceed with major elective noncardiac surgery provided that appropriate intraoperative and postoperative hemodynamic monitoring is used.[7]

Mitral Regurgitation. Acute mitral regurgitation can occur in the setting of myocardial infarction, trauma, or infective endocarditis. Chronic mitral regurgitation is typically associated with degenerative mitral valve disease (including mitral valve prolapse), rheumatic heart disease, ischemic heart disease, and cardiomyopathies. Chronic mitral regurgitation progresses very gradually. Symptoms develop relatively late, and typically only after onset of left ventricular dysfunction. Associated symptoms are initially vague, but progress to fatigue, dyspnea, and atrial fibrillation with disease progression.

On auscultation, patients with mitral regurgitation usually have a holosystolic murmur heard best at the cardiac apex (see Table 31.8). The murmur grade is somewhat correlated with the severity of mitral regurgitation in primary mitral valve disease (e.g., degenerative mitral valve disease), but not in secondary functional regurgitation (e.g., ischemic heart disease, cardiomyopathies). Although auscultation by a cardiologist can help determine mitral regurgitation (based on the presence or absence of a late systolic or holosystolic murmur in the mid-left thorax), the accuracy of auscultation by noncardiologists is uncertain.[26] Thus, an echocardiogram is helpful for any patient with a suspicious systolic murmur. Chronic mitral regurgitation is generally well tolerated perioperatively, unless other valvular lesions (e.g., mitral stenosis) or left ventricular dysfunction coexist. Consistent with these observations, limited prior research suggests that patients with mitral regurgitation have increased risks of cardiovascular complications, but not mortality.[177] Current guidelines suggest that patients with asymptomatic severe mitral regurgitation can proceed to major elective noncardiac surgery provided that appropriate intraoperative and postoperative hemodynamic monitoring is available.[7] Prophylaxis for infective endocarditis is no longer recommended.[173]

Mitral Valve Prolapse. Mitral valve prolapse is characterized by the systolic billowing of an abnormally thickened mitral valve leaflet into the left atrium, with or without coexistent mitral regurgitation. Diagnostic criteria for mitral valve prolapse have evolved to the current definition based on echocardiography alone, namely ≥ 2 mm billowing of any portion of the mitral leaflets above the annular plane in the long axis view.[178] It is the common cause of isolated mitral regurgitation requiring surgical repair in high-income countries. Nonetheless, only 4% of patients with mitral valve prolapse have severe valvular regurgitation, with most affected individuals having mild, trace, or no mitral regurgitation.[179] The condition may be primary (i.e., myxomatous degeneration) or secondary (e.g., associated with Marfan syndrome, Ehlers-Danlos syndrome, and osteogenesis imperfecta). Nonspecific symptoms (e.g., atypical chest pain, palpitations, dyspnea, exercise intolerance, dizziness) have been attributed, albeit unreliably, to mitral valve prolapse—in what has been termed as the "mitral valve prolapse syndrome."

On auscultation, these patients may have a systolic click and a mid-systolic murmur at the cardiac apex (that intensifies with a Valsalva maneuver). Auscultation by a cardiologist can help diagnose mitral valve prolapse (based on the presence or absence of a systolic click and murmur); however, the accuracy of auscultation by noncardiologists is uncertain.[26] From the perioperative perspective, the key issue is to differentiate patients with clinically significant mitral valve regurgitation from those with an incidental finding of prolapse that does not warrant further evaluation. Thus, echocardiography may be helpful to further investigate murmurs suspected of representing significant mitral regurgitation. Prophylaxis for infective endocarditis is no longer recommended.[173]

Tricuspid Regurgitation. Tricuspid regurgitation is a common valvular abnormality, with 70% of normal adults exhibiting a small degree of tricuspid regurgitation on echocardiography. Since it is usually asymptomatic and not easily audible on physical examination, tricuspid regurgitation is most commonly noted as an incidental echocardiographic finding. Significant tricuspid regurgitation is most commonly caused by dilatation of the right ventricle and tricuspid annulus (i.e., secondary disease). Causes of secondary tricuspid regurgitation include left-sided heart failure, mitral valve disease (stenosis or regurgitation), primary pulmonary disease (e.g., pulmonary hypertension), left-to-right intracardiac shunts (e.g., atrial septal defect, ventricular septal defect), pulmonary artery stenosis, and right ventricle disease (e.g., arrhythmogenic right ventricular dysplasia). Tricuspid regurgitation is less commonly caused by processes directly affecting the tricuspid valve (i.e., primary disease), such as Ebstein anomaly, infective endocarditis (typically in intravenous drug users), rheumatic heart disease, carcinoid syndrome, connective tissue disorders (e.g., Marfan syndrome), myxomatous degeneration, or direct injury (e.g., permanent pacemaker or ICD lead). Certain drugs—namely anorectics (fenfluramine, phentermine) and pergolide (dopamine agonist)—have also been associated with primary tricuspid regurgitation.

Patients with mild or moderate tricuspid regurgitation are generally asymptomatic. Individuals with severe regurgitation may report pulsations in the neck (related to distended jugular veins), as well as symptoms of right-sided heart failure (e.g., ascites, peripheral edema) and underlying conditions (e.g., pulmonary hypertension). Relevant findings on physical examination include distended jugular veins, hepatomegaly, ascites, dependent edema, and a right ventricular heave on chest palpation. On auscultation, tricuspid regurgitation causes a holosystolic murmur that is heard best at the midsternal border or subxiphoid area. Nonetheless, the murmur is often absent or very soft, even with severe regurgitation. The intensity of the murmur can be increased using maneuvers that increase venous return (e.g., inspiration, abdominal pressure). Although auscultation by a cardiologist can help determine moderate-to-severe tricuspid regurgitation (based on the presence or absence of increased murmur intensity with inspiration or abdominal pressure), the accuracy of auscultation by noncardiologists is uncertain.[26] Thus, echocardiography may be helpful in a patient with a suspicious murmur, especially within the context of signs or symptoms of right-sided heart failure. The preoperative management of patients with severe tricuspid regurgitation should be guided by the presence of any underlying conditions, right-sided heart failure, and known or suspected pulmonary hypertension. Where indicated, perioperative management should be conducted collaboratively with a heart failure cardiologist or pulmonary hypertension specialist. Prophylaxis for infective endocarditis is no longer recommended.[173]

Hypertrophic Cardiomyopathy. Hypertrophic cardiomyopathy is a genetic disorder of the myocardium, which can result in dynamic left ventricular outflow tract obstruction, myocardial ischemia, diastolic dysfunction, and mitral regurgitation (related to systolic anterior motion of the mitral valve leaflets). Most affected individuals have a relatively normal lifespan; however others are at risk for progressive heart failure, sudden cardiac death, and atrial fibrillation. Most patients with hypertrophic cardiomyopathy are asymptomatic. When symptoms are present, they are quite variable, and not well correlated with the extent of LVH or outflow tract obstruction. Typical associated symptoms include fatigue, exertional dyspnea, atypical or angina chest pain, exertional presyncope or syncope, and palpitations. Symptomatic patients may be prescribed long-term medical therapy with negative inotropic agents (i.e., β-blockers, verapamil, disopyramide). Other symptomatic individuals with severe left ventricular outflow tract obstruction may require intervention with either surgical myectomy or alcohol septal ablation. Some patients may also undergo ICD insertion if they are deemed high-risk for sudden cardiac death.

Although the physical examination in a patient with hypertrophic cardiomyopathy may be normal, the classic finding on auscultation (see Table 31.8) is a mid-systolic murmur that increases with maneuvers to decrease ventricular size (e.g., Valsalva maneuver) and decreases with maneuvers to increase ventricular size (e.g., passive leg raise). Auscultation by a cardiologist can help rule in or rule out hypertrophic cardiomyopathy (based on decreased murmur intensity with passive leg elevation or increased murmur intensity with shifts from a squatting to standing position), however, the accuracy of auscultation by noncardiologists is uncertain.[26] Accordingly, an echocardiogram should be obtained if a patient has a personal (or family) history of exertional syncope or cardiac arrest; a suspicious murmur is found on auscultation; or concerning ECG findings (i.e., LVH, ST-segment abnormalities, T-wave abnormalities) are observed in an otherwise healthy nonhypertensive patient. In general, patients with hypertrophic cardiomyopathy can safely undergo most low-risk and intermediate-risk noncardiac surgical procedures, especially with close hemodynamic monitoring and management. Medical therapy (e.g., β-adrenergic blockers, verapamil) should be continued perioperatively, but prophylaxis for infective endocarditis is no longer recommended.[173] Appropriate perioperative management should be instituted for any patient who has an associated ICD.

Prosthetic Heart Valves. In patients with prosthetic heart valves, the preoperative evaluation should determine the underlying indication that led to valve replacement; type, age, and current status of the valve prosthesis; need for long-term anticoagulation entailed by the valve prosthesis; and planned perioperative anticoagulation management plan. The anesthesiologist should review the most recent echocardiogram, and order a repeat echocardiogram if there are any signs or symptoms suggestive of valve dysfunction (e.g., new onset heart failure).[167] In addition, a recent complete blood count may be helpful since these patients may have a valve-related hemolytic anemia.

Anticoagulation with a vitamin K antagonist (e.g., warfarin) is required for 3 to 6 months after open surgical bioprosthetic valve implantation, after which patients can be transitioned to aspirin therapy alone (75-100 mg daily).[167] Life-long aspirin therapy is recommended for patients who have undergone TAVR, as well as clopidogrel (75 mg daily) for the first 6 months in all patients and vitamin K antagonists for the first 3 months in select individuals.[173] Conversely, patients with mechanical prosthetic valves require life-long therapy with both aspirin and vitamin K antagonists.[167] Importantly, DOACs—such as dabigatran, rivaroxaban, edoxaban, or apixaban—should not be used for anticoagulation therapy in patients with mechanical heart valves.[167] In general, decisions about temporary preoperative discontinuation of anticoagulants, duration of anticoagulant discontinuation, need for "bridging" therapy with a shorter-acting drug, and type of bridging agent (intravenous heparin or LMWH) should be made in conjunction with the treating cardiologist and surgeon. Current guidelines make recommendations for bridging therapy largely based on the location of the mechanical heart valve and nature of planned surgery (Box 31.4).[173] Prophylaxis for infective endocarditis is recommended for

BOX 31.4 Recommendations for Preoperative Bridging Anticoagulation Therapy in Patients With Mechanical Heart Valves

Class I (Recommended)

- Continuation of vitamin K antagonist anticoagulation with a therapeutic INR is recommended in patients with mechanical heart valves undergoing minor procedures (e.g., dental extractions, cataract removal) where bleeding is easily controlled.
- Temporary interruption of vitamin K antagonist anticoagulation, without bridging agents while the INR is subtherapeutic, is recommended in patients with a bileaflet mechanical AVR and no other risk factors* for thrombosis who are undergoing invasive or surgical procedures.

Class IIa (Is Reasonable)

- Bridging anticoagulation therapy during the time interval when the INR is subtherapeutic preoperatively is reasonable on an individualized basis—with the risks of bleeding weighed against the benefits of thromboembolism prevention—for patients who are undergoing invasive or surgical procedures with a (i) mechanical AVR and any thromboembolic risk factor, (ii) older-generation mechanical AVR, or (iii) mechanical MVR.

*Risk factors include atrial fibrillation, previous thromboembolism, hypercoagulable condition, older-generation ball-cage or tilting disc mechanical valve, left ventricular systolic dysfunction, and ≥ 2 mechanical valves.

AVR, Aortic valve replacement; *INR*, international normalized ratio; *MVR*, mitral valve replacement.

From Nishimura RA, Otto CM, Bonow RO, et al. 2017 AHA/ACC Focused Update of the 2014 AHA/ACC Guideline for the Management of Patients With Valvular Heart Disease: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Circulation.* 2017;135:e1159–e1195.

specific procedures (see section on "Infective Endocarditis Prophylaxis").[173]

Infective Endocarditis Prophylaxis

Patients at risk for infective endocarditis (e.g., valve replacement, complex congenital heart disease, previous endocarditis) and scheduled for procedures with the potential for transient bacteremia must be identified preoperatively. Current guidelines have dramatically scaled back the indications for prophylaxis. For example, current ACC/AHA guidelines recommended prophylaxis only for patients who are both at increased risk of developing infective endocarditis and also experiencing adverse outcomes from endocarditis (Box 31.5).[173] These target patient subgroups are also with those identified in the most recent ESC guidelines.[180] Prophylaxis is required when eligible patients undergo dental procedures that involve manipulation of gingival tissue, manipulation of the periapical region of teeth, or perforation of the oral mucosa. Prophylaxis is not required when these same individuals undergo nondental procedures (e.g., transesophageal echocardiography, gastroscopy, colonoscopy, cystoscopy, dermatological procedures), unless there is active infection at the procedure site.[173]

Rhythm Disturbances on the Preoperative Electrocardiogram

Arrhythmias and conduction disturbances are common during the perioperative period. Supraventricular and ventricular arrhythmias are associated with increased perioperative risk, both because of the arrhythmias themselves and because they are markers for cardiopulmonary disease. Uncontrolled atrial fibrillation (i.e., causing symptoms or hemodynamic compromise) and high-risk ventricular tachyarrhythmias (see section on "Ventricular Arrhythmias") are high-risk conditions that warrant postponement of elective surgery until evaluation and stabilization are complete. Rapid atrial fibrillation (rates > 100 beats/min), symptomatic bradycardia, or high-grade heart block (e.g., third-degree heart block) also warrants postponement of elective procedures to facilitate evaluation, stabilization, and possible cardiology evaluation.

First-degree atrioventricular (AV) block is defined as a PR interval exceeding 0.20 ms with an associated heart rate of 50 to 100 beats/min; it is considered generally benign. Second-degree heart block is defined by a PR interval exceeding 0.20 ms and the presence of some blocked atrial beats (resulting in a dropped or missing QRS complex after a P wave). There are two types of second-degree block. Mobitz type I block (also called Wenckebach block) is characterized by progressive lengthening of the PR interval until the dropped beat occurs. It is a more benign block that is related to AV nodal delay, easily responsive to atropine, and unlikely to progress to complete heart block. Mobitz type II block is characterized by a fixed and prolonged PR interval that does not change before the dropped QRS complex. It is related to an infranodal block, capable of progressing to complete heart block, and generally treated with a pacemaker (unless it is due to a reversible cause such as ischemia or drugs). Third-degree AV block or complete heart block, which is characterized by complete dissociation between the atrial and ventricular beats, requires pacemaker placement unless a reversible source is identified. A prolonged QT interval should prompt an evaluation of electrolytes (including magnesium and calcium), and search for any potentiating drugs. Syncope, presyncope, or a family history of sudden death in a patient with a prolonged QT interval mandates a cardiology consultation (see section on "Long QT Syndrome").

Three factors determine the need for permanent pacemaker treatment for an arrhythmia, namely whether the arrhythmia is associated with symptoms, where the conduction abnormality is located, and whether a reversible cause can be identified. Indications for perioperative pacemaker placement are the same as those in nonsurgical patients (common indications listed in Box 31.6).[181] In general, pacemaker placement is required for symptomatic bradycardia or conduction delays that lead to syncope or presyncope. Conduction disease below the AV node (i.e., in the His-Purkinje system) is also generally less stable and likely benefits from permanent pacemaker placement. The presence of such conduction disease is suggested by a normal or minimally prolonged PR interval, Mobitz type II block, and QRS complex abnormalities (BBB, fascicular block, or both).

BBBs can be classified as complete versus incomplete, and right bundle branch block (RBBB) versus LBBB. BBBs may be normal variants in some individuals, or the result of age-related fibrosis in the conduction system. Nonetheless, they can be associated with important underlying conditions. For example, LBBB may be related to structural heart disease (i.e., hypertensive heart disease, IHD, cardiomyopathies, valvular heart disease), while RBBB may be the result of elevated right ventricular pressures (i.e., pulmonary hypertension, cor pulmonale, pulmonary embolism), prior radiation exposure, myocarditis, and structural heart disease (i.e., IHD, cardiomyopathies, valvular heart disease, congenital heart disease). The presence of a BBB is not itself an indicator of increased perioperative cardiovascular risk,[182] especially after accounting for known clinical risk factors.[100] Nonetheless, data from the nonoperative

BOX 31.5 **Cardiac Conditions for Which Endocarditis Prophylaxis Is Recommended**

Previous infective endocarditis
Prosthetic cardiac valves, including transcatheter-implanted prostheses, and homografts
Prosthetic material used for cardiac valve repair, such as annuloplasty rings and chords
Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
Repaired congenital heart disease, with residual shunts or valvular regurgitation at the site of or adjacent to the site of a prosthetic patch or prosthetic device
Cardiac transplant with valve regurgitation due to a structurally abnormal valve

Prophylaxis is reasonable before dental procedures that involve manipulation of gingival tissue, manipulation of the periapical region of teeth, or perforation of the oral mucosa.

From Nishimura RA, Otto CM, Bonow RO, et al. 2017 AHA/ACC Focused Update of the 2014 AHA/ACC Guideline for the Management of Patients With Valvular Heart Disease: A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Circulation.* 2017;135: e1159–e1195.

setting suggest that a recent onset or new diagnosis of a bundle branch should prompt a more extensive evaluation for undiagnosed cardiovascular disease. For example, LBBB is associated with increased risks of incident cardiovascular disease,[183] cardiovascular mortality,[183] and mortality in the nonoperative setting.[184] Additionally, RBBB is associated with increased risks of mortality in patients with suspected IHD, known IHD, and heart failure.[185,186] Based on this approach, if preoperative evaluation does not suggest significant pulmonary disease, IHD, structural heart disease, or Brugada syndrome (see section on "Brugada Syndrome"), no further preoperative evaluation of an isolated asymptomatic RBBB is warranted. Conversely, RBBB in a patient with known or suspected pulmonary disease (e.g., pulmonary hypertension) may suggest severe respiratory or vascular compromise; thus, consideration should be given to pulmonary evaluation and echocardiography if intermediate- or high-risk surgery is planned.

Atrial Fibrillation. Atrial fibrillation is a common arrhythmia characterized by a variable irregular ventricular response, and an absence of regular or organized atrial activity. The arrhythmia is classified as paroxysmal (i.e., terminates spontaneously or with intervention within 7 days of onset), persistent (i.e., fails to self-terminate within 7 days), long-standing persistent (i.e., lasts more than 12 months), or permanent (i.e., persistent atrial fibrillation where a joint decision has been made by the patient and clinician to no longer pursue a rhythm control strategy).[187] Atrial fibrillation can occur in the absence of any structural heart disease (previously termed "lone atrial fibrillation"), or in combination with underlying disorders. In high-income countries, hypertension and ischemic heart disease are the most common underlying disorders, while in low and middle-income countries, rheumatic heart disease is a very common associated condition. Other associated conditions include valvular heart disease, heart failure, hypertrophic cardiomyopathy, congenital heart disease, obesity, diabetes mellitus, CKD, and increased age. Potentially reversible acute triggers for atrial fibrillation are hyperthyroidism and recent surgery (especially cardiac or thoracic surgery).

Affected individuals are at elevated risk for death, heart failure, thromboembolic events (i.e., stroke), and hospitalization. In the nonoperative setting, treatment involves ventricular rate control, consideration of rhythm control to restore sinus rhythm, and prevention of systemic embolization. In large randomized trials, strategies that focused on heart rate control versus rhythm control have shown similar effects on the risks of stroke or death.[188,189] The CHA_2DS_2-VASc score (Table 31.10) can be used to estimate the long-term systematic embolization risk in patients with atrial fibrillation.[190] Based on this score, patients can be classified as low-risk (0 points: 0.2% annualized stroke rate), intermediate-risk (1 point: 0.6% annualized stroke rate), or high-risk (≥2 points: >2.2% annualized stroke rate).[191] Based on strong randomized controlled trial data,[192] current ACC/AHA guidelines recommend long-term oral anticoagulation for patients with nonvalvular atrial fibrillation (i.e.,

BOX 31.6 Common Indications for a Permanent Pacemaker

Class I Indications

- Sinus bradycardia with symptoms due to the bradycardia (typically seen with heart rates less than 40 bpm or with frequent sinus pauses)
- Symptomatic chronotropic incompetence (i.e., impaired heart rate response to exercise)
- Third-degree AV block
- Advanced second-degree AV block (block of ≥2 consecutive *P* waves)
- Symptomatic Mobitz I or II second-degree AV block
- Mobitz II second-degree AV block with a widened QRS or chronic bifascicular block, regardless of symptoms
- Exercise-induced second- or third-degree AV block

Class II Indications

- Sinus bradycardia (heart rate < 40 bpm) with symptoms suggestive (but not definitively so) of bradycardia
- Sinus node dysfunction with a history of unexplained syncope
- Chronic heart rates < 40 bpm in an awake but minimally symptomatic patient
- Asymptomatic Mobitz II second-degree AV block with a narrow QRS interval
- Bifascicular or trifascicular block associated with syncope possibly related to intermittent third-degree heart block
- First-degree AV block with a very long PR interval (which effectively leads to AV dissociation and hemodynamic compromise)

AV, Atrioventricular; *bpm,* beats per minute.
Class I Indications: *Permanent* pacing is definitely beneficial, useful, and effective.
Class II Indications: *Permanent* pacing may be indicated but there is conflicting evidence and/or divergence of opinion.
From Epstein AE, DiMarco JP, Ellenbogen KA, et al. 2012 ACCF/AHA/HRS focused update incorporated into the ACCF/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *Circulation.* 2013;127:e283–e352.

TABLE 31.10 Scoring Scheme for the CHA_2DS_2-VASc Score

Risk Factor	Points
Heart Failure Associated signs and symptoms, or left ventricular systolic dysfunction	1
Hypertension	1
Age ≥ 75 years	2
Diabetes mellitus	1
Previous stroke, transient ischemic attack, or thromboembolism	2
Vascular Disease Myocardial infarction, peripheral artery disease, or aortic plaque	1
Age 65–74 years	1
Female sex	1

unrelated to mitral stenosis or prosthetic heart valves) and CHA_2DS_2-VASc scores of 2 or more, and support omitting anticoagulation in individuals with CHA_2DS_2-VASc scores of zero.[187] There is more uncertainty about the best treatment for individuals with CHA_2DS_2-VASc scores of 1. Consistent with this uncertainty, ACC/AHA guidelines indicate that (1) oral anticoagulant therapy, (2) aspirin therapy, or (3) omitting anticoagulation are all reasonable approaches in these intermediate-risk patients.[187] With respect to specific anticoagulant therapy, patients can be prescribed either a vitamin K antagonist (e.g., warfarin) or DOAC (e.g., dabigatran, rivaroxaban, edoxaban, apixaban) as reasonable options for patients with nonvalvular atrial fibrillation.

Although atrial fibrillation has typically been ignored during preoperative cardiac risk assessment, accumulating evidence challenges this approach in two main respects. Specifically, preexisting atrial fibrillation appears to be an indicator of increased perioperative risk. For example, in a large international multicenter prospective cohort study, preexisting atrial fibrillation was associated with an elevated risk of postoperative cardiovascular events (i.e., stroke, cardiovascular death, myocardial injury, heart failure, or cardiac arrest),[193] but not death.[77] In an American population-based retrospective cohort study, chronic atrial fibrillation was associated with a significantly higher risk of perioperative stroke.[194]

The preoperative evaluation of patients with atrial fibrillation focuses on underlying conditions (e.g., ischemic heart disease), complications (e.g., heart failure, stroke), rate or rhythm control strategies, and anticoagulation strategies. Patients with rapid ventricular rates (>100 beats/min) typically require rate control before any elective surgery. Patients with both atrial fibrillation and slow ventricular rate without rate-controlling medications may have sick sinus syndrome. They should be questioned regarding any previous episodes of syncope or presyncope. Any long-term β-adrenergic blockers, digoxin, calcium channel blockers, or antiarrhythmic medications should be continued.

The critical component for preoperative planning for most patients with atrial fibrillation is appropriate perioperative management of long-term anticoagulants. This management should ideally be conducted collaboratively with the treating physician and responsible surgeon. There are three overarching issues, namely (1) whether temporary preoperative discontinuation is needed, (2) when oral anticoagulants should be discontinued, and (3) whether bridging therapy with LMWH is required.[195] It is reasonable to continue vitamin K antagonist therapy if an individual does not have patient-related risk factors for bleeding (e.g., liver disease, abnormal renal function, prior bleeding complications), and is scheduled for a procedure without important bleeding risk (e.g., dental extraction, simple cutaneous procedures, pacemaker insertion). Otherwise, patients should have their anticoagulant medications temporarily discontinued before surgery, including all patients who are receiving DOACs or might need neuraxial anesthesia. If a decision to temporarily discontinue oral anticoagulants is made, vitamin K antagonists should be stopped 5 days before surgery. A longer discontinuation period may be needed for initial international normalized ratio (INR) values greater than 3.0. Ideally, the INR should be rechecked within 24 hours before surgery,[195] and a low dose of oral vitamin K administered for any INR result above 1.5. The timing of preoperative discontinuation of DOACs (Table 31.11) should be guided by the specific drug prescribed, expected procedural bleeding risk, renal function (based on estimated glomerular filtration rate [GFR]), and planned use of neuraxial anesthesia.[195,196] The ongoing multicenter Perioperative Anticoagulant Use for Surgery Evaluation prospective cohort study is expected to provide more high-quality data on the safety of a further simplified strategy for preoperative discontinuation of DOACs (Table 31.12).[197]

Accumulating evidence indicates that most patients with nonvalvular atrial fibrillation do not require bridging therapy if their anticoagulant therapy is temporarily discontinued before surgery. For example, in the multicenter Bridging Anticoagulation in Patients Who Require Temporary Interruption of Warfarin Therapy for an Elective Invasive Procedure and Surgery (BRIDGE) randomized trial, placebo was non-inferior to LMWH bridging therapy with respect to risks of arterial thromboembolism following perioperative interruption of vitamin K antagonist therapy.[198] In addition, bridging therapy led to increased risks of major bleeding. When interpreting the trial data, the challenge pertains to their generalizability to patients in clinical practice. For example, about 62% of the 1884

participants in the BRIDGE trial had an expected 1-year stroke rate less than 5% (i.e., equivalent to CHA_2DS_2-VASc score ≤ 4), while about 14% had an expected 1-year stroke rate over 10% (equivalent to CHA_2DS_2-VASc score ≥ 7). To help clinicians better navigate clinical decision making, the ACC published a 2017 expert consensus report on perioperative anticoagulation management in nonvalvular atrial fibrillation.[195] In the case of vitamin K antagonist therapy, the recommended approach is to omit bridging therapy in low-risk patients who have CHA_2DS_2-VASc scores of 4 or less and no prior stroke, TIA, or systemic embolization. Conversely, bridging therapy should be considered for high-risk patients with CHA_2DS_2-VASc scores of 7 or more, recent (i.e., prior 3 months) stroke, TIA, or systemic embolization. For intermediate-risk patients (i.e., those not meeting either the low-risk or high-risk criteria), bridging therapy should be considered if there is no significant bleeding risk and a more remote time (more than 3 months) of stroke, TIA, or systemic embolization. Bridging therapy is generally not needed after preoperative interruption of DOACs because of their relatively short half-lives.

Supraventricular Arrhythmias. Supraventricular tachycardia can result from rapidly firing ectopic atrial foci with rapid conduction through the AV node, or from a reentry mechanism. Pathways for a reentry mechanism typically involve the AV node-Purkinje system and an accessory reentry pathway. In a reentry mechanism, the cycle self-perpetuates because conduction occurs down one pathway and up the other. Pharmacologic AV blockade (i.e., adenosine, verapamil, β-adrenergic blockers) can help slow the ventricular rate in most supraventricular tachycardias, with the exception of Wolff-Parkinson-White (WPW) syndrome. WPW syndrome is characterized by the presence of an accessory pathway (bundle of Kent) that permits *both* retrograde and antegrade conduction. Antegrade conduction over the accessory pathway results in a short PR interval (<0.12 ms) and a slurring of the upstroke of the QRS complex (termed a delta wave). Individuals with WPW syndrome are predisposed to supraventricular tachycardia. Additionally, treatment of supraventricular tachycardia in affected individuals with AV nodal blocking drugs can paradoxically increase conduction over the accessory pathway, thus potentially causing ventricular fibrillation. Thus, *acute* supraventricular tachycardia in these patients should be treated with electrical cardioversion (especially if hemodynamically unstable), ibutilide,[199] or procainamide. Long-term management of WPW syndrome typically involves catheter ablation of the recurrent accessory pathway. Long-term antiarrhythmic medications should be continued perioperatively in patients with known supraventricular tachycardia.[9]

Ventricular Arrhythmias. Ventricular ectopic beats can be differentiated from atrial ectopic beats by a wide QRS complex (>0.12 ms) and absence of an associated P-wave. To help predict the risk of sudden death, ventricular arrhythmias may be classified based on the type of rhythm disturbance and presence of underlying heart disease.

- *Benign* ventricular arrhythmias include isolated ventricular premature beats (VPBs) without associated heart disease. Affected individuals have no increased risk of sudden cardiac death, and do not need further cardiology evaluation.
- *Potentially lethal* arrhythmias include more than 30 VPBs per hour, or nonsustained ventricular tachycardia in association with underlying heart disease. Affected individuals are at moderately high risk of sudden cardiac arrest and may benefit from an ICD. They also require cardiology evaluation and echocardiography, along with the possible need for cardiac stress testing, coronary angiography, and electrophysiology testing.
- *Lethal* arrhythmias include sustained ventricular tachycardia, ventricular fibrillation, and VPBs associated with underlying heart disease, depressed cardiac function, and hemodynamic compromise. Affected individuals are at high risk for sudden cardiac arrest, and likely benefit from an ICD. They also require cardiology evaluation and echocardiography, along with possible cardiac stress testing, coronary angiography, and electrophysiology testing. In general, reversible causes of ventricular arrhythmias (e.g., hypokalemia, ischemia, acidosis, hypomagnesemia, drug toxicity, endocrine dysfunction) should be sought out and treated. Any long-term antiarrhythmic medications should be continued perioperatively.[9]

Long QT Syndrome. The long QT syndrome (LQTS) is a myocardial repolarization disorder associated with a prolonged QT interval. The QT interval is measured using a 12-lead ECG (preferably leads II and V5) from the onset of the QRS complex to the end of the T wave. Since the interval varies inversely with heart rate, a corrected QT interval (QT_c) can be calculated, with the most common formula being:

$$QT_c = \frac{\text{QT interval}}{\sqrt{\text{RR interval}}}$$

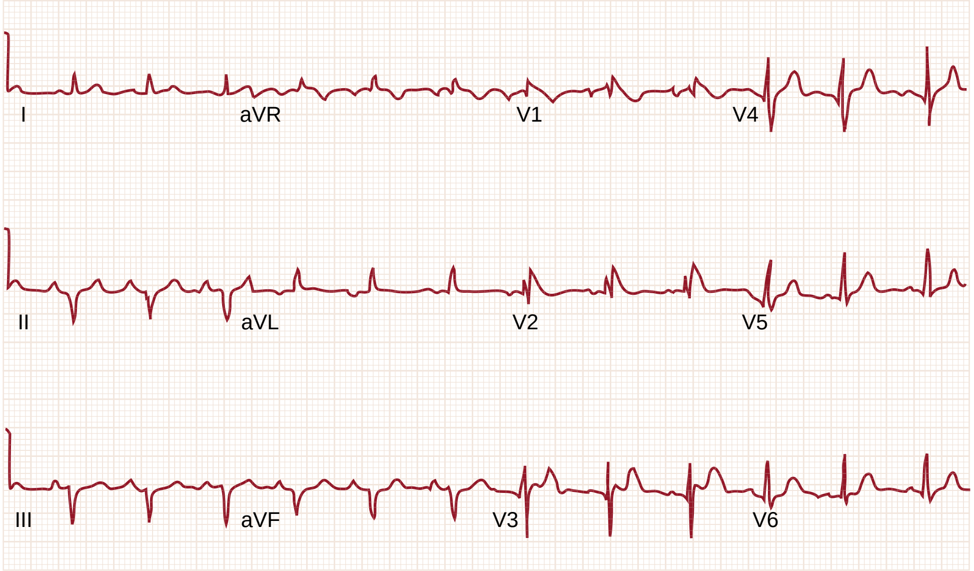

Fig. 31.7 Typical 12-lead electrocardiogram in a patient with Brugada syndrome.

In adults, an abnormally prolonged QTc is defined as a value exceeding the 99th percentile. The QTc is prolonged if exceeding 0.48 seconds in women and 0.47 seconds in men.[200] Individuals with LQTS are predisposed to developing *torsades de pointes*, a polymorphic ventricular tachycardia with frequent variations of the QRS axis or morphology. Affected patients are generally asymptomatic in the absence of arrhythmias. Conversely, after the onset of an arrhythmia, they may develop palpitations, syncope, seizures, and sudden cardiac death.

LQTS may be either congenital (i.e., genetic) or acquired. Causes of acquired LQTS include antiarrhythmic drugs (e.g., quinidine, sotalol, dofetilide, ibutilide), psychotropic medications (e.g., haloperidol, methadone), erythromycin, cisapride, and metabolic abnormalities (i.e., hypokalemia, hypomagnesemia, hypocalcemia). Notably, while amiodarone does markedly prolong the QT interval, it is rarely associated with *torsades de pointes* except in association with hypokalemia. The 2010 ACC/AHA scientific statement on the prevention of *torsades de pointes* suggests that QT_c be documented before initiation or after an increased dose of QT-prolonging drugs, and thereafter at least every 8 to 12 hours.[200] Other components of treatment for LQTS include β-adrenergic blockers (congenital LQTS), ICD implantation, and correction of underlying metabolic disorders.

Brugada Syndrome. Brugada syndrome is a rare cause of sudden cardiac arrest that occurs in the absence of structural heart disease. It is an autosomal dominant disorder that is more common in men, rarely diagnosed in children, and often affects individuals of Asian ethnicity. Patients usually have normal findings on echocardiography, stress testing, and cardiac magnetic resonance imaging (MRI). The most significant clinical manifestations are ventricular arrhythmias, syncope, and sudden death. Patients may also be at increased risk of atrial arrhythmias, especially atrial fibrillation. Brugada syndrome is characterized by an ECG with pseudo-RBBB and persistent ST-segment elevation in leads V_1 to V_3 (Fig. 31.7). Unlike usual RBBB, a widened S wave in the left lateral leads is usually absent in Brugada syndrome. In some patients, these ECG changes are transient and provoked by medications. Asymptomatic patients who have these typical ECG features but no other associated clinical criteria have been described as having "Brugada pattern." The website www.brugadadrugs.org lists drugs that are associated with adverse events in Brugada syndrome. These medications include some commonly used anesthetic drugs, such as propofol and bupivacaine. The syndrome has no proven pharmacologic treatment; indeed, class I antiarrhythmic medications (e.g., flecainide, procainamide) and β-adrenergic blockers can worsen the risk of lethal arrhythmias. ICD implantation is the standard of care for Brugada syndrome.

Cardiovascular Implantable Electronic Devices

Cardiovascular implantable electronic devices (CIEDs), which include both permanent pacemakers and ICDs, are very common. For example, in the United States alone, about 190,000 permanent pacemakers and 145,000 ICDs are implanted every year (see Chapter 38).[201,202] The preoperative evaluation should characterize the device with respect to type, age, manufacturer, model number, current settings, and timing of recent interrogation. Patients frequently carry a manufacturers' identification card with some of this relevant information. Permanent pacemaker capabilities are usually classified using a five-letter code (Table 31.13).[203] The anesthesiologist should also evaluate any coexisting cardiac disease because patients with CIEDs invariably have conditions such as heart failure, IHD, valvular heart disease, or potentially lethal arrhythmias—all of which have perioperative implications. It is especially important to note device features (e.g., rate modulation) that can malfunction with perioperative electromagnetic and other interferences. Sources of electromagnetic interference during the perioperative period include electrocautery (especially monopolar), radiofrequency ablation, lithotripsy devices, and radiation therapy, while direct mechanical interference can occur with guidewire movement during

TABLE 31.13 Pacemaker Nomenclature

From Bernstein AD, Daubert JC, Fletcher RD, et al. The revised NASPE/BPEG generic code for antibradycardia, adaptive-rate, and multisite pacing. North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group. *Pacing Clin Electrophysiol*. 2002;25:260–264.

central venous catheter insertion.[204] These sources of interference can result in CIED malfunction, such as inappropriate ICD discharge or inappropriate changes in pacing rates. Especially during delicate surgical procedures (e.g., intracranial, spinal, ocular), an unexpected ICD discharge with movement of the patient can have catastrophic results.

In general, the anesthesiologist conducting a preoperative evaluation of a patient with a CIED should collaboratively plan perioperative management with the relevant CIED care team (Box 31.7).[7,204] The CIED care team has been defined as the physicians and physician extenders who monitor the patient's CIED function. Ideally, patients with CIEDs should have these devices interrogated preoperatively, with recommendations that this be performed within the prior 6 months for an ICD, prior 12 months for a permanent pacemaker, and prior 3 to 6 months for any CRT device. Key issues for consideration when planning the perioperative care of a patient with a CIED include whether the patient has an ICD, whether the patient is pacemaker-dependent, and what happens with magnet placement over the CIED. In general, a magnet suspends antitachyarrhythmia therapy in most ICDs, and switch pacemakers (but not ICDs) to an asynchronous pacing mode. There is some disagreement among guidelines whether to place a magnet over the CIED during the intraoperative period,[204,205] versus arrange for temporary device reprogramming (i.e., switch pacemaker to asynchronous mode, and disable antitachyarrhythmia ICD).[206] Especially given the complexity of newer generation CIEDs, routine magnet use should not be viewed as an alternative for appropriate preoperative preparation. Collaboration with the CIED care team is the preferred approach for managing these patients in an individualized manner. Preoperative recommendations for CIEDs are presented in Box 31.8. In addition, these patients require a preoperative ECG. A chest radiograph is not mandatory before surgery but can reveal the device location and manufacturer's code.

Peripheral Artery Disease

PAD, which is defined as atherosclerosis of the large-sized and medium-sized noncardiac arterial vasculature, affects about 200 million people worldwide.[207] PAD is diagnosed based on an ankle-brachial index (ABI or ratio of ankle-to-arm systolic blood pressure) of less than 0.90.[208] The disease generally affects lower extremity vessels more than upper extremity vessels. PAD progresses variably across individuals, from an initially asymptomatic phase to intermittent claudication (i.e., extremity pain with activity) to critical limb ischemia. Risk factors for PAD include increased age, smoking, hypertension, diabetes mellitus, CKD, and known atherosclerosis in other sites (e.g., IHD). Conversely, patients with PAD likely have atherosclerosis in other sites (e.g., heart, brain). For example, a systematic review in the nonoperative setting found a prevalence of IHD in individuals with PAD ranged from 60% based on cardiac stress testing to 90% based on coronary angiography.[209] Individuals meeting diagnostic criteria for PAD (i.e., ABI < 0.90) have elevated risks for subsequent myocardial infarction, acute stroke, or cardiovascular death in the nonoperative setting.[210] PAD is also a marker of increased risk in surgical patients. An ABI less than 0.90 is independently associated with an increased risk of cardiovascular complications after noncardiac surgery.[211] Known PAD is also associated with elevated risks of mortality after major noncardiac surgery.[77,78] In addition, claudication related to PAD generally

BOX 31.7 Proposed Principles for Cardiovascular Implantable Electronic Device Management

The perioperative management of CIEDs must be individualized to the patient, type of CIED, and procedure being performed. A single recommendation for all CIED patients is not appropriate.

The CIED care team is defined as the physicians and physician extenders who monitor the CIED function of the patient.

The surgical or procedural team should communicate with the CIED care team to identify the type of procedure and likely risk of EMI.

The CIED care team should communicate with the procedure team to deliver a prescription for the perioperative management of patients with CIEDs.

For most patients, the prescription can be made from a review of the records of the CIED clinic. A small percentage of patients may require consultation from CIED specialists if the information is not available.

It is inappropriate to have industry-employed allied health professionals independently develop this prescription.

CIED, Cardiovascular implantable electronic devices; *EMI,* electromagnetic interference.

From Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) Expert Consensus Statement on the perioperative management of patients with implantable defibrillators, pacemakers and arrhythmia monitors: facilities and patient management: executive summary. *Heart Rhythm.* 2011;8:e1–e18.

BOX 31.8 **Preoperative Recommendations for Cardiovascular Implantable Electronic Devices**

- Inactivation of ICDs is not absolutely necessary for all procedures
- Not all pacemakers need to be altered to pace asynchronously in all patients or for all procedures
- Pacemakers can be reprogrammed or magnets can be used to force pacemakers to pace asynchronously to prevent inhibition
- ICDs can be reprogrammed or magnets can be used to inhibit ICD arrhythmia detection and tachyarrhythmia functions
- Magnets can/will *not* force pacemakers in ICDs to pace asynchronously
- Inactivation of ICDs is recommended for all procedures above the umbilicus involving electrocautery or radiofrequency ablation
- It is preferable to change to asynchronous pacing in pacemaker-dependent patients for procedures involving electrocautery or radiofrequency ablation above the umbilicus

The procedure team provides the following information to the CIED team:

- Type of procedure
- Anatomic site of procedure
- Patient position during procedure
- Will electrocautery (and type of cautery) be used?
- Are there other sources of EMI?
- Other issues such as likelihood of damage to leads (e.g., chest procedures), anticipated large blood loss, and surgery in close proximity to CIED

The CIED care team provides the following information to the procedure team:

- Type of device (e.g., pacemaker, ICD)
- Indication for device (e.g., sick sinus syndrome, primary or secondary prevention of lethal arrhythmias)
- Programming (e.g., pacing mode, rate, rate responsive, heart rates for shock delivery)
- Is the patient pacemaker-dependent, and what is the underlying heart rate/rhythm?
- Magnet response
    - Pacing rate
    - Is the device responsive to a magnet?
    - Will ICD functions resume automatically with magnet removal?
    - Does magnet need to be placed off-center?

CIED, Cardiovascular implantable electronic device; *EMI*, electromagnetic interference; *ICD*, implantable cardioverter-defibrillator.

Modified from Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) Expert Consensus Statement on the perioperative management of patients with implantable defibrillators, pacemakers and implantable monitors: facilities and patient management: executive summary. *Heart Rhythm*. 2011;8:e1–e18.

limits functional capacity and thereby masks the symptoms of underlying IHD or heart failure.

The preoperative evaluation of PAD should encompass related symptoms (e.g., intermittent claudication, rest pain), risk factors (e.g., hypertension, diabetes mellitus, smoking, CKD), and associated comorbidities (e.g., IHD, CVD). Arterial blood pressure should be measured in both upper extremities, along with the presence of peripheral arterial pulses. Auscultation for bruits over the abdomen and femoral arteries, as well as palpation for abdominal masses, should be part of the vascular examination. Typical preoperative laboratory testing includes an ECG and blood sampling for a complete blood count, creatinine concentration, and glucose concentration. These individuals may often need further specific workup for IHD with testing such as natriuretic peptides and cardiac stress testing (see section on "Ischemic Heart Disease"). Depending on concomitant risk factors and cardiovascular medications, patients may be on long-term therapy with aspirin, $P2Y_{12}$ inhibitors (e.g., clopidogrel), and DOACs. DOACs should be temporarily discontinued before surgery (see section on "Atrial Fibrillation"). In most cases, $P2Y_{12}$ inhibitor therapy should also be interrupted before surgery, with the possible exception of cases with very recent coronary stent implantation (see section on "Coronary Stents"). As a general strategy for patients undergoing noncardiac surgery, continuing aspirin perioperatively does not prevent cardiovascular complications except in those with drug-eluting coronary stents,[136] but leads to an increased risk of major bleeding (which is a risk factor for perioperative stroke).[132] Nonetheless, selective continuation of aspirin should be considered in patients undergoing vascular surgery (to mitigate risks of bypass graft occlusion), as well as those with high-risk IHD, prior PCI, or recent stroke (i.e., previous 9 months).[212]

PULMONARY DISORDERS

See Chapters 13 and 53.

Asthma

The Global Initiative for Asthma (http://ginasthma.org), describes asthma as a "*heterogeneous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation.*" These episodes of airflow obstruction within the lung are often reversible, either spontaneously or with treatment. The airway obstruction can be precipitated by irritants (e.g., smoke), allergens, infections, medications, or airway instrumentation. Worldwide, it is estimated that asthma afflicts more than 300 million people, and is responsible for one in every 250 deaths.[213] Asthma is classified as intermittent, persistent mild, persistent moderate, and persistent severe, based on symptoms, nighttime awakenings, short-acting bronchodilator requirement, functional impairment, and pulmonary function test (PFT) abnormalities. Although spirometry is the preferred diagnostic test for asthma, a normal result does not exclude asthma. Typical findings on PFTs are a reduction in the ratio of the forced expiratory volume in 1 second (FEV_1) to forced vital capacity (FVC)—with a ratio below 0.7 being indicative of airflow obstruction. Importantly, normal initial PFT results do not necessarily exclude asthma. If results are normal but a diagnosis of asthma is still strongly suspected, a methacholine challenge test or a trial of bronchodilator therapy should be performed. Patients with mild well-controlled asthma have no greater perioperative risk than do individuals without asthma.[214] In addition, PFTs, while helping to establish the diagnosis of asthma, generally have no perioperative prognostic value in these patients.

In a patient with known asthma, the anesthesiologist should inquire about dyspnea, chest tightness, cough (especially nocturnal), recent exacerbations (with associated triggers), therapy (especially corticosteroids), prior hospitalizations, prior emergency department visits, prior critical care unit admissions, prior need for endotracheal intubation, and recent upper respiratory tract infections (see section on "Upper Respiratory Tract Infections"). It is helpful to ask patients to compare their current asthma symptoms to their "normal" or "best" status based on symptoms, exercise tolerance, and medication requirements. The physical examination should assess the quality of breath sounds, quantity of air movement, degree of wheezing, and oxygen saturation by pulse oximetry. The degree of wheezing does not always correlate with the severity of bronchoconstriction. With severe obstruction, airflow is dangerously restricted, and wheezing diminishes. Wheezing is common in asthma but it is not specific for the disease. For example, wheezing may be present in chronic obstructive pulmonary disease (COPD), gastroesophageal reflux disease, vocal cord dysfunction, tracheal stenosis, bronchial stenosis, cystic fibrosis, allergic bronchopulmonary aspergillosis, and heart failure. Observing the degree of accessory muscle use can also help gauge the severity of bronchoconstriction.

Arterial blood gases are not necessary unless the patient is having a severe acute exacerbation. Patients taking oral corticosteroids should have their blood glucose checked. Chest radiography is needed only if an infection or pneumothorax is suspected. Bronchodilators, corticosteroids (inhaled and oral), and any antibiotics must be continued on the day of surgery. β-adrenergic agonists are a useful prophylactic intervention to lower the risk of bronchospasm after induction of anesthesia. This therapy can be supplemented with a short preoperative course of oral corticosteroids (prednisone 20 mg-60 mg daily for 3-5 days) in any newly diagnosed or poorly controlled asthmatic patient.[215] Importantly, some asthmatics on chronic corticosteroid treatment may need perioperative "stress dose steroids" (see section on "Hypothalamic-Pituitary-Adrenal Disorders").

Chronic Obstructive Pulmonary Disease

COPD is a chronic respiratory disease that affects 175 million people worldwide, and causes 3 million deaths every year.[216] It is characterized by persistent airflow obstruction that occasionally is partially reversible (see Chapters 13 and 53). It may be the result of smoking, environmental pollutants (e.g., air pollution), α_1-antitrypsin deficiency, chronic infections, and long-standing asthma. The Global Initiative for Chronic Obstructive Lung Disease describes COPD as a "*common, preventable, and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases*" (http://www.goldcopd.org). COPD includes subtypes such as "chronic bronchitis" and "emphysema." Chronic bronchitis is defined as a chronic productive cough for 3 months in each of 2 successive years in a patient in whom other causes of chronic cough (e.g., bronchiectasis) have been excluded. Emphysema refers to pathologic structural changes in the lung that can occur with COPD, including enlargement of airspaces distal to the terminal bronchioles, as well as destruction of these airspace walls. The severity of COPD is classified based on both spirometry findings and symptoms. Once a patient has evidence of airway obstruction on spirometry (FEV_1/FVC ratio < 0.7), mild FEV_1 airflow limitation is at or greater than 80% of predicted, *moderate* limitation is FEV_1 between 50% and 79% of predicted, *severe* limitation is FEV_1 between 30% and 49% of predicted, and *very severe* limitation is FEV_1 is less than 30% of predicted. Symptom severity is classified separately using validated scales.[217] A COPD exacerbation is defined as "*an acute worsening of respiratory symptoms that result in additional therapy*" (http://www.goldcopd.org).

The preoperative evaluation of patients with COPD is similar to that of patients with asthma, with an additional emphasis on signs of recent infection (e.g., changes in sputum amount or color). A barrel chest and pursed-lip breathing also suggest advanced disease. COPD is a known risk factor for postoperative pulmonary complications (see section on "Postoperative Pulmonary Complications").[218] Nonetheless, there is no established threshold of COPD severity indicative of highly prohibitive perioperative risk. In general, PFTs are not useful for estimating perioperative risk in patients with COPD, with the exception of individuals undergoing lung resection surgery (see Chapter 53 and section on "Patients Scheduled for Lung Resection"). In general, preoperative PFTs are indicated when there is uncertainty as to whether the patient's lung function is optimized, or uncertainty as to the underlying basis for unexplained dyspnea. Patients who are hypoxic, or require supplemental oxygen, may benefit from further testing, including arterial blood gas measurement, in addition to routine measurement of oxygen saturation using pulse oximetry. A chest radiograph is useful only if infection or bullous disease is suspected. A key goal in the preoperative preparation of a patient with COPD is optimizing pulmonary function before any elective surgery. Accordingly, patients with a recent exacerbation may require more intensive bronchodilator treatment, brief courses of antibiotics or oral corticosteroids, and possible deferment of elective surgery. Smoking cessation should be encouraged for any ongoing smokers (see section on "Smokers and Second-Hand Smoke Exposure"). Additionally, consideration can be given to preoperative inspiratory muscle training and physiotherapy in high-risk patients, and discussion about the potential respiratory benefits of neuraxial anesthesia or analgesia (see section on "Postoperative Pulmonary Complications"). Inhalers and other long-term medications for COPD should be continued on the day of surgery, and individuals on chronic corticosteroid treatment may need "stress dose steroids" (see section on "Hypothalamic-Pituitary-Adrenal Disorders").

Restrictive Pulmonary Disorders

Restrictive lung disease is characterized by a reduced total lung capacity and may be related to both pulmonary or extrapulmonary conditions. Pulmonary causes include idiopathic interstitial pneumonia, prior lung resection, pulmonary fibrosis, and interstitial lung disease secondary to connective tissue disease. Extrapulmonary causes include chest wall limitations (e.g., kyphoscoliosis, obesity, ankylosing spondylitis), muscle dysfunction (e.g., muscular dystrophies, myasthenia gravis, diaphragm paralysis), and pleural disease (e.g., mesothelioma, effusion, pneumothorax). In a patient with suggestive symptoms or history of associated diseases, a chest radiograph and PFTs can help establish the diagnosis. Typically, the FEV_1 and the FVC are reduced proportionally such that the FEV_1/FVC ratio is normal (i.e., > 0.7). Preoperative PFTs can also help assess for acute or progressive worsening of known restrictive lung disease; however, routine testing is not necessary in the absence of clinical suspicion. These patients are also at risk of pulmonary hypertension that may not be recognized because of overlapping symptoms with restrictive lung disease. Thus, echocardiography may also be indicated to investigate causes of worsening symptoms in a patient with known restrictive lung disease.

Patients Scheduled for Lung Resection

Most patients scheduled for lung resection operations have underlying lung disease (this topic is covered in more detail in Chapter 53). Spirometry is useful in estimating risk and excluding patients who are highly likely to lack adequate pulmonary reserve after the planned resection (see Chapter 53). Current American College of Chest Physicians (ACCP) guidelines recommend measurement of both FEV_1 and diffusing capacity for carbon monoxide (D_{LCO}) in all patients being considered for lung resection surgery.[219] The amount of residual lung function after resection can be estimated by using a combination of spirometry and radionuclide quantitative lung scanning. The predicted postoperative FEV_1 (PPO FEV_1) is predicted by multiplying the preoperative FEV_1 by the percentage of perfusion to the nonoperative lung or lung region:

$$\text{PPO FEV}_1 = \text{Preoperative FEV}_1 \times \frac{\text{Perfusion to nonresected lung}}{\text{Total perfusion to lungs}}$$

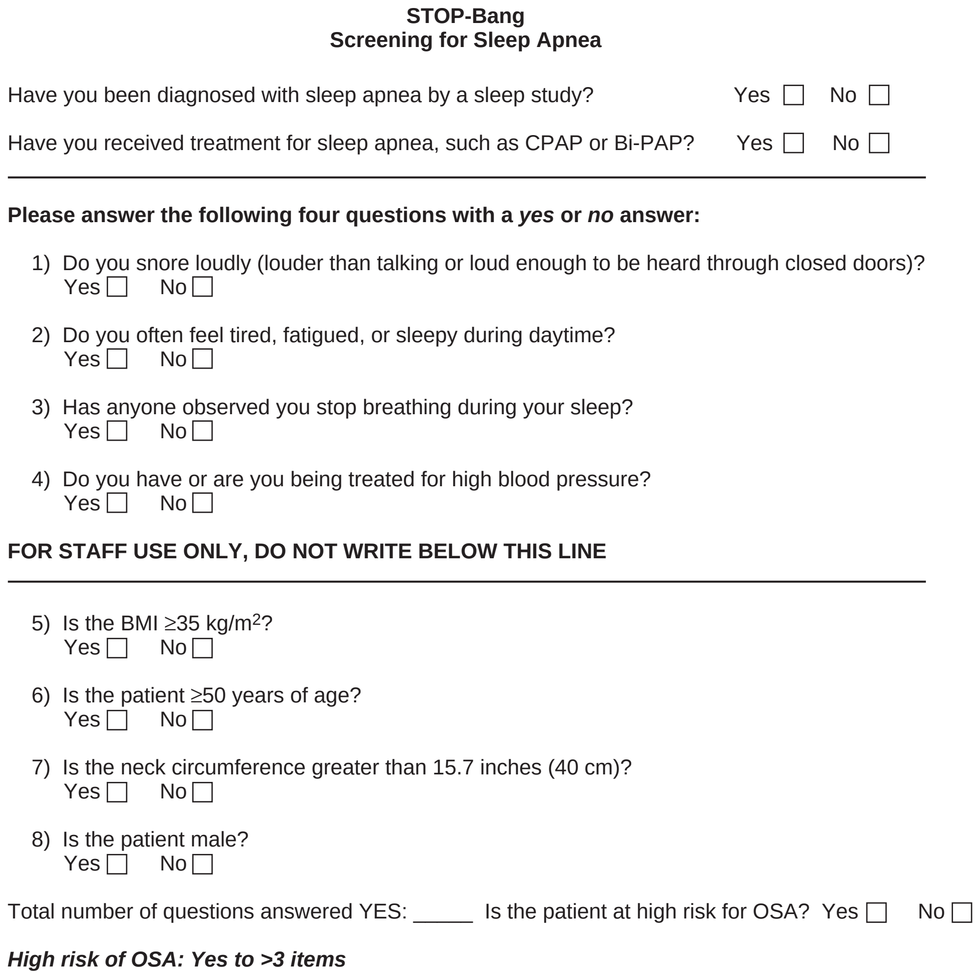
The PPO D_{LCO} is calculated using an analogous equation for preoperative D_{LCO}. Patients with both PPO FEV_1 and PPO D_{LCO} values exceeding 60% of predicted are considered low-risk and can generally proceed directly to surgery. If either value is within the range of 30% to 60% of predicted, simple objective exercise testing with a shuttle walk test or symptom limited stair climbing test is recommended. For individuals with poor performance on these simple tests (i.e., < 400 m on shuttle walk test or < 22 m on stair climbing test), as well as for individuals with either PPO FEV_1 or PPO D_{LCO} values less than 30% predicted, the ACCP guidelines recommend CPET to measure peak oxygen consumption (VO_2 peak).[219] A preoperative VO_2 peak greater than 20 mL/kg/min is consistent with low perioperative risk, 10 to 20 mL/kg/min is consistent with moderate risk, and less than 10 mL/kg/min is consistent with high risk. Nonsurgical options should be considered in high-risk scenarios, while shared decision making should be incorporated in any intermediate-risk scenarios.

Obstructive Sleep Apnea

In North America, the prevalence of sleep-disordered breathing is 9% among females aged 30 to 60 years of age, and 24% among males in the same age group (see Chapter 10).[220] OSA is the most common type of sleep-disordered breathing, with varying prevalence across age groups, ethnicities, and countries. Recent North American estimates suggest that it afflicts about 9% of females aged 50 to 70 years, and 17% of males in this same age group.[221] OSA is characterized by recurrent upper airway collapse during sleep that leads to reduced or complete cessation of airflow, despite ongoing breathing efforts. Affected individuals develop intermittent hypercapnia, intermittent hypoxemia, and fragmented sleep. Risk factors for OSA include increased age, male sex, obesity, smoking, pregnancy, heart failure, end-stage renal disease, and craniofacial abnormalities. The diagnosis of OSA is based on the presence of symptoms, such as nonrestorative sleep, snoring, hypertension, and the frequency of sleep-related respiratory events during polysomnography or home sleep apnea testing. Once diagnosed, disease severity is typically characterized by the apnea-hypopnea index (AHI), which is the number of apneic and hypopneic episodes per hour of sleep. Mild OSA is defined by 5 to 15 episodes per hour, moderate disease by 16 to 30 episodes per hour, and severe disease by more than 30 episodes per hour. OSA is associated with an increased prevalence of systemic hypertension, pulmonary hypertension, IHD, heart failure, cardiac arrhythmias (i.e., atrial fibrillation, bradyarrhythmias, ventricular ectopy), stroke, type 2 diabetes mellitus, obesity hypoventilation syndrome, and nonalcoholic fatty liver disease. The main effective treatments for OSA in the nonoperative setting are continuous positive airway pressure (CPAP) and weight loss.[222-224]

Most cases of OSA in surgical patients remain undiagnosed at the time of surgery.[225] Screening questionnaires can help, in part, address this problem. For example, the eight-item STOP-Bang questionnaire is a straightforward validated tool to screen for OSA in preoperative evaluation clinics (Fig. 31.8).[226] Surgical patients with scores of 2 or less are at very low risk (negative likelihood ratio 0.24 for AHI ≥ 5), and those with scores of 5 or more are at increased risk (positive likelihood ratio 1.8 for AHI ≥ 5).[226] Since individuals with scores of 3 to 4 are in an indeterminate zone, additional screening criteria have been proposed for this subgroup, including serum bicarbonate concentration level at 28 mmol/L or greater,[227] and differentially weighting responses to the questionnaire.[228] There is some uncertainty as to the operational burden of screening all surgical patients for OSA, especially since the positive likelihood ratio for a higher STOP-Bang score is not particularly high. A reasonable option may be to apply screening in higher-risk populations, such as individuals with obesity, associated comorbidities, and known or suspected difficult intubation characteristics.

Patients with OSA are at increased perioperative risk because of the sleep disorder itself and associated comorbidities. Mask ventilation, direct laryngoscopy, endotracheal intubation, and fiberoptic visualization of the airway are more difficult in patients with OSA (see Chapter 44). In addition, these patients are also more sensitive to the respiratory depressant effects of opioids. In general, patients with OSA have elevated risks of perioperative airway obstruction, hypoxemia, atelectasis, pneumonia, cardiovascular complications, and prolonged hospitalizations.[229] There is uncertainty as to how much of this increased risk is explained by OSA itself, versus associated comorbidities (e.g., IHD, heart failure, diabetes mellitus, obesity). For example, some cohort studies that found that patients with known OSA, or patients screened as being high-risk for OSA, were not at elevated risk of mortality or postoperative hypoxemia, after accounting for coexisting comorbidities.[77,230,231]



STOP-Bang
Screening for Sleep Apnea

Have you been diagnosed with sleep apnea by a sleep study? Yes ☐ No ☐

Have you received treatment for sleep apnea, such as CPAP or Bi-PAP? Yes ☐ No ☐

Please answer the following four questions with a *yes* or *no* answer:

1) Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?
Yes ☐ No ☐

2) Do you often feel tired, fatigued, or sleepy during daytime?
Yes ☐ No ☐

3) Has anyone observed you stop breathing during your sleep?
Yes ☐ No ☐

4) Do you have or are you being treated for high blood pressure?
Yes ☐ No ☐

FOR STAFF USE ONLY, DO NOT WRITE BELOW THIS LINE

---

5) Is the BMI ≥35 kg/m^2?
Yes ☐ No ☐

6) Is the patient ≥50 years of age?
Yes ☐ No ☐

7) Is the neck circumference greater than 15.7 inches (40 cm)?
Yes ☐ No ☐

8) Is the patient male?
Yes ☐ No ☐

Total number of questions answered YES: _____ Is the patient at high risk for OSA? Yes ☐ No ☐

High risk of OSA: Yes to >3 items

Fig. 31.8 Stop-Bang questionnaire to screen patients for obstructive sleep apnea. (From Chung F, Yegneswaran B, Liao P, et al. STOP Questionnaire: a tool to screen patients for obstructive sleep apnea. *Anesthesiology*. 2008;108:812–821.)

Preoperative evaluation focuses on characterizing all cases of known OSA, and selectively identifying patients at risk for undiagnosed OSA. In addition, associated comorbidities should be investigated and optimized as deemed clinically appropriate. For example, echocardiography may be indicated if undiagnosed heart failure or pulmonary hypertension is suspected. For patients with known OSA, the anesthesiologist should inquire about known disease severity, document current treatment, and instruct the patient to bring their CPAP equipment or oral appliances on the day of surgery (so that therapy can be restarted promptly after surgery).

Pulmonary Hypertension

Pulmonary hypertension is defined as a persistent mean pulmonary artery pressure of 25 mm Hg or more at rest. The condition may occur in isolation or with associated medical conditions. Based on the World Health Organization, pulmonary hypertension is classified into 5 groups (Box 31.9).[232] Idiopathic and heritable pulmonary arterial hypertension (formerly called primary pulmonary hypertension) are relatively rare. Other more common forms occur with a variety of diseases including cardiac, pulmonary, liver, thromboembolic, and collagen vascular diseases (e.g., scleroderma, systemic lupus erythematosus [SLE]). Pulmonary hypertension is also associated with human immunodeficiency virus (HIV) infection, anorectic drug exposure (e.g., fenfluramine), OSA, and chronic liver disease (especially with portal hypertension).

Patients with pulmonary hypertension have a high rate of perioperative morbidity and mortality.[233-235] Hypoxia, hypercarbia, hypothermia, vasoconstrictor use, and increased sympathetic tone (even from anxiety) during the perioperative period increase pulmonary vascular resistance, with the potential for acute decompensation with right-sided heart failure. Occult pulmonary hypertension is more problematic than the fully recognized disease because symptoms may be attributed to other diseases, and perioperative decompensation may occur unexpectedly. Current American and European guidelines recommend that affected patients be managed collaboratively with a pulmonary hypertension specialist team during the perioperative period, and that they undergo surgery at centers with requisite expertise.[7,9]

It may be challenging to detect pulmonary hypertension *de novo* during preoperative evaluation. The initial symptoms of pulmonary hypertension are usually nonspecific and insidious. Diagnosis is also typically delayed, with about 20% of patients having symptoms for more than 2 years prior to a formal diagnosis.[236] Typical initial symptoms

BOX 31.9 Classification Scheme for Pulmonary Hypertension

Pulmonary Arterial Hypertension

1. Idiopathic pulmonary arterial hypertension
2. Heritable pulmonary arterial hypertension
3. Drug-induced or toxin-induced pulmonary arterial hypertension
4. Associated with other conditions
    (a). Connective tissue disease
    (b). Congenital heart disease
    (c). Portal hypertension
    (d). Human immunodeficiency virus infection
    (e). Schistosomiasis
5. Pulmonary venoocclusive disease and/or pulmonary capillary hemangiomatosis
6. Persistent pulmonary hypertension of newborn

Pulmonary Hypertension Related to Left-heart Disease

1. Left ventricular systolic dysfunction
2. Left ventricular diastolic dysfunction
3. Valvular heart disease
4. Extrinsic compression of central pulmonary veins
5. Congenital or acquired obstruction of the left heart inflow or outflow tract, and congenital cardiomyopathies

Pulmonary Hypertension Related to Lung Disease or Hypoxemia

1. Chronic obstructive pulmonary disease
2. Interstitial lung disease
3. Other pulmonary diseases with mixed restrictive and obstructive pattern
4. Sleep disordered breathing
5. Alveolar hypoventilation disorders
6. Developmental lung disease
7. Chronic exposure to high altitude

Chronic Thromboembolic Pulmonary Hypertension

Pulmonary Hypertension with Unclear Multifactorial Etiology

1. Hematologic disorders (chronic hemolytic anemia, myeloproliferative disorders, splenectomy)
2. Systemic disorders (sarcoidosis, pulmonary histiocytosis, lymphangioleiomyomatosis)
3. Metabolic disorders (glycogen storage disease, Gaucher disease, thyroid disorders)
4. Other conditions (tumor obstruction, fibrosing mediastinitis, chronic kidney disease, segmental pulmonary hypertension

From: Simonneau G, Gatzoulis M, Adiata I, et al. Updated clinical classification of pulmonary hypertension. *J Am Coll Cardiol*. 2013;62: D34–D41.

are exertional dyspnea, lethargy, and fatigue. With disease progression, symptoms related to right ventricular overload develop—these symptoms include exertional chest pain, exertional syncope or presyncope, upper abdominal pain (i.e., liver congestion), and dependent edema. Physical examination may reveal a split S$_2$ with a loud second component, right ventricular heave, tricuspid regurgitation murmur, ascites, hepatomegaly, jugular venous distention, and peripheral edema. An ECG and echocardiogram are useful in patients with suspected pulmonary hypertension, and those with moderate-to-severe known disease. Typical ECG findings include right axis deviation, RBBB, right ventricular hypertrophy, and tall R waves in leads V$_1$ and V$_2$. Right atrial hypertrophy and "P-pulmonale" may be present in severe pulmonary hypertension, with peaked P waves, usually in leads II, III, aVF, and V$_1$. An echocardiogram is the initial screening test of choice for pulmonary hypertension. It can estimate pulmonary arterial pressures, assess right ventricular function, identify left-sided heart failure, and detect structural heart disease (e.g., valvular heart disease, congenital heart disease). Patients with significant echocardiographic findings may require subsequent right and left cardiac catheterizations, especially given the potential inaccuracy of estimating right-sided pressures by echocardiography alone. Other useful laboratory tests include complete blood count, electrolyte concentrations, creatinine concentrations, and liver function tests (i.e., liver congestion or drug-related side effects).

Patients with pulmonary hypertension may be receiving treatment with diuretics, calcium channel blockers, supplemental oxygen, phosphodiesterase type 5 inhibitors (e.g., sildenafil, tadalafil), endothelin receptor antagonists (e.g., bosentan, ambrisentan), and prostacyclin pathway agonists (e.g., iloprost, epoprostenol). Some drugs are given by continuous intravenous infusions, and even momentary interruption of therapy can be catastrophic. In general, all these medications should be continued perioperatively.[7,9] Some patients may be anticoagulated. The timing of any preoperative anticoagulant discontinuation, and assessment for bridging therapy, should be made collaboratively with a pulmonary hypertension specialist team.

Smokers and Second-Hand Smoke Exposure

Tobacco exposure, either directly or through "second-hand" smoke, increases the risk of many perioperative complications, including respiratory, cardiac, and infectious events. Current smokers have elevated risks for a range of postoperative complications, including mortality, cardiac complications, pulmonary complications, acute stroke, and surgical site infections.[237,238] Overall, about two thirds of smokers want to quit.[239] The U.S. Public Health Service recommends that "*all physicians should strongly advise every patient who smokes to quit because evidence shows that physician advice to quit smoking increases abstinence rates*."[240] Even brief advice by a physician to quit smoking increases quit rates (relative risk 1.66; 95% CI, 1.42-1.94),[241] albeit from a very low baseline rate of 2% to 3%. Among intensive smoking cessation interventions, both behavioral counselling and medications have demonstrated efficacy, with evidence supporting further improvement in efficacy with combination therapy.[242] The main pharmacologic interventions for smoking cessation are nicotine replacement therapy (i.e., nicotine patches, gum, or lozenges), varenicline, and bupropion. Both bupropion and varenicline should be started at least 1 week before an attempt at quitting. Many hospitals, insurance companies, communities, and governmental agencies offer smoking cessation programs. Excellent advice and guidelines are available online (e.g., https://www.cdc.gov/tobacco/quit_smoking/index.htm and https://smokefree.gov) or via telephone (e.g., 1-800-QUIT-NOW in the United States).

Being scheduled for surgery is a "teachable moment" for promoting smoking cessation, with population-based survey data from the United States showing significant increases in smoking cessation rates after major surgery.[243] Within this context, interventions in the preoperative evaluation clinic result in higher rates of short-term smoking cessation (i.e., within 3-6 months after surgery).[244] Although there is uncertainty about the robustness of smoking cessation rates over the long term,[245] randomized controlled trials have demonstrated reduced nicotine dependence of up to 1 year postoperatively following perioperative smoking cessation interventions.[246,247]

The perioperative benefits of smoking abstinence are realized within the first year after cessation.[248] Nonetheless, there remains uncertainty regarding the minimum required period to accrue benefits. In previous systematic reviews, clinical benefits of preoperative smoking cessation were demonstrated only when it occurred at least 3 to 4 weeks before surgery.[249,250] These benefits include reduced risks for respiratory and wound healing complications. Despite an early study reporting an increased perioperative risk (this association was not statistically significant) in recent quitters,[251] a systematic review found no increased risk of adverse events with quitting smoking soon before surgical procedures (i.e., within 8 weeks).[252] Thus, motivated patients should be encouraged to quit smoking at any point before surgery. Quitting has many theoretical benefits, even within a few days before operation. Soon after a patient quits smoking, carbon monoxide levels decrease, thereby improving oxygen delivery and use. Cyanide levels decrease, which benefits mitochondrial oxidative metabolism. Other beneficial effects include lower nicotine levels (which improves vasodilatation) and clearance of many toxic substances that impair wound healing.

Upper Respiratory Tract Infections

Traditionally, elective surgical procedures were cancelled when patients, especially children, presented with current or recent upper respiratory tract infections. The concern pertains to associated airway hyperreactivity that predisposes patients to laryngospasm, bronchospasm, atelectasis, coughing, airway obstruction, hypoxia, stridor, and breath-holding.[253] Prior evidence suggests that this airway hyperreactivity lasts for 2 to 4 weeks after an upper respiratory tract infection.[253,254] Nonetheless, since most of these associated perioperative respiratory events are mild and easily managed with modern anesthesia care, cancellation is no longer routine. For patients with severe symptoms (e.g., high fever), especially in the presence of other health conditions (e.g., significant asthma, heart disease, immunosuppression), elective surgery should be postponed until 4 weeks after resolution of the infection. Conversely for mild or uncomplicated infections in otherwise healthy patients, it is reasonable to proceed with the planned surgery and avoid the inconvenience of a last-minute cancellation. The dilemma lies with patients between these two extremes, for whom decisions regarding the suitability to proceed should be made on an individualized basis.

Cystic Fibrosis

Cystic fibrosis is an autosomal recessive disease caused by altered chloride and water transport across epithelial cells. This genetic disorder can result in progressive chronic airway disease characterized by airway obstruction, destruction, and frequent pulmonary infections. Affected individuals can also develop exocrine pancreatic insufficiency (i.e., malnutrition, diabetes mellitus, pancreatitis), bowel obstruction, sinusitis, and liver disease (i.e., biliary cirrhosis, portal hypertension). The diagnosis is based on compatible clinical findings in at least one organ system (e.g., chronic airway disease, exocrine pancreatic insufficiency, chronic pansinusitis, cystic fibrosis) in a first-degree relative in combination with either biochemical (sweat chloride $\geq$ 60 mmol/L on two occasions) or genetic confirmation (presence of known disease-causing genetic mutations).[255]

The preoperative clinical evaluation should especially focus on respiratory, hepatic, and nutritional assessment. With respect to preoperative investigations, electrolyte levels, liver function tests, chest radiographs, and PFTs are useful. Collaborative perioperative management in conjunction with a pulmonologist or a cystic fibrosis specialist is ideal, with an important goal being optimization of pulmonary status (i.e., secretions, infections, bronchospasm) before surgery. Most medications for cystic fibrosis should be continued perioperatively.

Postoperative Pulmonary Complications

Postoperative pulmonary complications encompass several important clinical entities and these have been further defined in a recent systematic literature review and consensus-based process. Abbott and colleagues identified four standard outcome measures that are appropriate for widespread use in clinical trials of postoperative pulmonary complications, namely, pneumonia, atelectasis, acute respiratory distress syndrome, and aspiration.[256] In addition, the investigators proposed a new definition of postoperative pulmonary complications that incorporates the severity of the complication based on the degree of therapy required (e.g., supplemental oxygen, positive pressure ventilation).[256] There is considerable variation in how pulmonary outcome complications are defined and this is reflected in the inconsistent reporting of outcomes across studies and hinders interpretation of research findings. Despite the reporting inconsistencies, a reasonable estimate is that these complications develop in about 5% of patients undergoing nonthoracic surgery.[257,258]

Established risk factors for pulmonary complications pertain to two general domains: patient-level risk factors and procedure-related risk factors (Box 31.10).[218] Patient-level factors include general health status (e.g., ASA physical status [ASA-PS], functional dependency), smoking history, advanced age, COPD, preexisting pulmonary disease (e.g., recent infection, low oxygen saturation) pulmonary hypertension, anemia, heart failure, preexisting sepsis, poor nutritional status (e.g., albumin concentration), and obesity (BMI > 30 kg/m^2).[218,257,259,260] Notably absent from this list of patient-related factors are asthma, arterial blood gas results, or PFT results. The risk of complications is surprisingly low in patients who have well-controlled asthma or preoperative corticosteroid treatment.[214] The risk is higher in asthmatic patients with recent exacerbations, prior postoperative pulmonary complications, recent hospitalizations, or endotracheal intubations for asthma. Arterial blood gases are useful in predicting pulmonary function after lung resection operations, but do not estimate perioperative pulmonary risk. Findings on PFTs, such as the degree of FEV$_1$, are generally not predictive of pulmonary complications.[218] PFTs have clear roles in diagnosis ("*Is*

BOX 31.10 Selected Risk Factors for Postoperative Pulmonary Complications

Potential Patient-related Risk Factor

Advanced age
ASA-PS Class 2 or more
Congestive heart failure
Functionally dependent
Chronic obstructive pulmonary disease
Weight loss
Impaired sensorium
Cigarette use
Alcohol use
Abnormal findings on chest examination

Potential Procedure-related Risk Factor

Aortic aneurysm repair
Thoracic surgery
Abdominal surgery
Upper abdominal surgery
Neurosurgery
Head-and-neck surgery
Emergency surgery
Vascular surgery
General anesthesia
Perioperative transfusion

Potential Laboratory Test Risk Factor

Albumin concentration < 35 g/L
Chest radiograph abnormalities
BUN concentration > 7.5 mmol/L (> 21 mg/dL)

TABLE 31.14 Scoring Scheme for the ARISCAT[*] Perioperative Pulmonary Risk Index

Components of ARISCAT Score	Points Assigned
Age	
■ ≤50 years	0
■ 51–80 years	3
■ >80 years	16
Preoperative oxygen saturation	
■ ≥96%	0
■ 91%–95%	8
■ ≤91%	24
Respiratory infection in prior month	17
Preoperative anemia (<100 g/L)	11
Surgical incision location	
■ Peripheral	0
■ Upper abdominal	15
■ Intrathoracic	24
Duration of surgery	
■ ≤2 h	0
■ >2–3 h	16
■ >3 h	23
Emergency procedure	8
ARISCAT Score	**Risk of Pulmonary Complications[†]**
Low-risk: < 26 points	1.6%
Intermediate risk: 26–44 points	13.3%
High-risk: ≥ 45 points	42.1%

[*] Estimates risk of composite endpoint of respiratory infection, respiratory failure, pleural effusion, atelectasis, pneumothorax, bronchospasm, or aspiration pneumonitis.

ARISCAT, Assess Respiratory Risk in Surgical Patients in Catalonia group.

[†] Three patients were excluded because of a missing value in some variable.

dyspnea caused by lung disease or heart failure?") or informing management ("*Can dyspnea or wheezing be improved further?*"), but should not be used as a risk assessment tool or to deny a surgical procedure.[10,218] Procedure-related risk factors for pulmonary complications include the type of procedure (head-and-neck, thoracic, upper abdominal, aortic, neurosurgical), long-duration procedures, emergency procedures, general anesthesia, and residual neuromuscular blockade.[218,257]

Several preoperative clinical risk indices have been developed to estimate pulmonary risk.[34,35,257,259,260] Although these indices have reasonable predictive accuracy, they also have important limitations. Some only predict specific complication types (i.e., pneumonia vs. respiratory failure),[34,35,259,260] and others are too complex for easy clinical use.[34,35] The most straightforward, currently available index is likely the ARISCAT (Assess Respiratory Risk in Surgical Patients in Catalonia) score,[257] which has also been externally validated (Table 31.14).[261] The score classifies patients as low-risk, intermediate-risk, and high-risk strata.[257]

When high-risk patients are identified before surgery, the anesthesiologist has several available options to help decrease their perioperative pulmonary risk. These approaches include encouraging smoking cessation (see section on "Smokers and Second-Hand Smoke Exposure"), treatment of any recent asthma or COPD exacerbation, and treatment of any recent lower respiratory tract infection. These interventions may require medications (e.g., antibiotics, bronchodilators, corticosteroids), specialist referral (e.g., pulmonologists), or delay in the planned surgical procedure. There is accumulating evidence pointing to benefits from preoperative inspiratory muscle training and physiotherapy in high-risk patients undergoing cardiac or abdominal surgery.[262,263] The anesthesiologist can also use the preanesthesia evaluation to educate patients about the potential respiratory benefits of neuraxial anesthesia or analgesia,[19,264,265] and discuss options for less-invasive surgical procedures with the referring surgeon.

ENDOCRINE DISORDERS

Diabetes Mellitus

Diabetes mellitus afflicts about 420 million people worldwide.[266] The two main disease categories are type 1 diabetes (previously called "insulin-dependent diabetes" or "juvenile-onset diabetes") and type 2 diabetes (previously called "non–insulin dependent diabetes" or "adult-onset diabetes").[267] Type 1 diabetes, which accounts for about

5% to 10% of all cases of the disease, is the result of autoimmune destruction of pancreatic β-cells. Affected individuals have an absolute deficiency of insulin, but normal sensitivity to insulin. Since the disease has a typically early onset at a young age, and is often difficult to control, adults with type 1 diabetes are at risk of premature vascular disease, such as IHD, nephropathy, retinopathy, and peripheral neuropathy. They are also at risk of diabetic ketoacidosis. Type 2 diabetes is characterized by insulin resistance and a relative (but not absolute) deficiency in insulin. Most affected individuals are obese and seldom prone to ketoacidosis. Diabetes mellitus is associated with multiorgan dysfunction, including IHD, heart failure (independent of associated IHD), CVD, CKD, peripheral neuropathy, autonomic neuropathy (e.g., postural hypotension, gastroparesis), retinopathy, and reduced joint mobility (e.g., reduced cervical mobility affecting airway management). In the perioperative setting, diabetes mellitus is a risk factor for postoperative complications, including cardiac events,[97] acute kidney injury (AKI),[268,269] and surgical site infections.[270] Insulin therapy is the main treatment for type 1 diabetes mellitus, either as multiple daily injections or a continuous subcutaneous insulin infusion. In the case of type 2 diabetes, multiple treatment options are available, including nonpharmacologic therapy (i.e., diet, weight loss, exercise), metformin, sulfonylureas (e.g., glyburide, glipizide), repaglinide, glucagon-like peptide-1 (GLP-1) agonists (e.g., liraglutide), sodium-glucose cotransporter 2 (SGLT2) inhibitors (e.g., empagliflozin), dipeptidyl peptidase-4 (DPP-4) inhibitors (e.g., sitagliptin, saxagliptin, linagliptin, alogliptin), and insulin.

During the preoperative evaluation of a patient with diabetes mellitus, the anesthesiologist should document the disease type (i.e., type 1 vs. type 2), current usual glycemic control, history of hypoglycemic episodes, current therapy, and the severity of any end-organ complications. Given the effects of diabetes mellitus on other organ systems, the history and physical examination should especially focus on the cardiovascular, renal, and neurologic systems. Inquiries about postural dizziness, early satiety, and postprandial vomiting can help assess for any autonomic neuropathy. The physical examination should include an evaluation of pulses, skin breakdown, and joint (especially cervical spine) mobility. Informative preoperative laboratory tests include an ECG and blood sampling for electrolyte, creatinine, and blood glucose concentrations. To help better estimate renal function, an estimated GFR should be calculated (see section on "Kidney Disease"). Since patients are not typically fasting when they are evaluated in a preoperative evaluation clinic, glucose concentrations measured in the clinic cannot be used to evaluate general glycemic control. A diary of multiple glucose values (preprandial and postprandial) at varying times of the day is more informative for estimating the adequacy of therapy. Alternatively, a glycosylated hemoglobin (HbA_{1c}) concentration can help characterize the average plasma glucose concentration within the prior 3 months. Among surgical patients, preoperative HbA_{1C} is more informative than patients' self-reported history, fasting blood glucose concentrations, and random blood glucose concentrations in identifying preexisting poor glycemic control.[271] In the nonoperative setting, the American Diabetes Association recommends a target HbA_{1c} concentration under 7% for most diabetic patients. Although preoperative HbA_{1c} is correlated with postoperative glycemic control,[272] its role as a predictor of postoperative complications is largely restricted to diabetic patients undergoing orthopedic or vascular surgery.[273] Recently updated guidelines from the National Institute for Health and Care Excellence (NICE) in the United Kingdom[274] recommend offering HbA_{1c} testing to diabetic surgical patients who have not been tested in the prior 3 months, and ensuring the recent HbA_{1c} test results be included in referral materials from patients' primary care providers.

In the perioperative setting, the goals of glycemic management are to avoid hypoglycemia, prevent ketoacidosis, and avoid marked hyperglycemia. Tight perioperative glucose control in the immediate perioperative period is controversial. While aggressive management of hyperglycemia may theoretically help decrease postoperative complications, these theoretical clinical benefits of intraoperative intensive glucose control have not been observed in randomized trials of surgical patients.[275] Ideally, all diabetic patients should have their surgery as an early morning case to minimize any disruption of their diabetic management fasting. Normal treatment regimen for most noninsulin diabetic medications (metformin, sulfonylureas, repaglinide, GLP-1 agonists, DPP-4 inhibitors) should be continued until (and inclusive of) the day before surgery but held on the morning of surgery. The possible exception pertains to SGLT2 inhibitors, which have been associated with euglycemic diabetic ketoacidosis in the postoperative setting.[276] Thus, some guidelines recommend that the medications be discontinued at least 24 hours before elective surgery.[277] Diabetic patients should discontinue *short-acting* insulin while fasting. The exception pertains to patients with continuous subcutaneous insulin infusion pumps. These individuals should continue their infusion at the lowest basal rate, which is usually the nighttime fasting rate. With respect to management of *intermediate-acting* or *long-acting* insulin on the day of surgery, there is no uniform consensus on optimal perioperative protocols. A reasonable approach is for patients with type 1 diabetes mellitus to take a small amount (one third to one half) of their usual morning dose of intermediate-acting or long-acting insulin (e.g., lente, isophane) to avoid diabetic ketoacidosis. Patients with type 2 diabetes mellitus can either take no insulin or up to one half of their usual dose of intermediate-acting, long-acting, or combination (e.g., 70/30 preparations) insulin on the morning of surgery.

Thyroid Disease

Thyroid hormones are important for metabolism and its regulation. Mild to moderate thyroid dysfunction probably has minimal perioperative impact.[278,279] The major concern pertains to significant hyperthyroidism or hypothyroidism, which appears to increase perioperative risk. Symptoms and signs of hypothyroidism and hyperthyroidism can be subtle and nonspecific, especially with milder disease in older adults. Hyperthyroid individuals may manifest tachycardia, arrhythmias, palpitations, tremors, weight loss, and diarrhea. Patients with hypothyroidism may demonstrate hypotension, bradycardia, lethargy, weight gain, depressed cardiac function, pericardial effusions, and impaired ventilatory response to hypoxia or hypercarbia. Patients may also have goiters with related symptoms such as dysphagia, dyspnea, wheezing, and orthopnea. Individuals with hyperthyroidism due to Graves disease may also demonstrate proptosis.

The preoperative evaluation should clarify the patient's current medical therapy as well as any recent changes. In patients with known thyroid disease, additional preoperative thyroid function testing is not needed if the patient is on a stable medication dose and was assessed as being euthyroid within the previous 6 months. If additional preoperative testing is clinically indicated, thyroid-stimulating hormone (TSH) assays are best to evaluate for hypothyroidism, while free triiodothyronine (T_3), free thyroxine (T_4), and TSH levels are useful in hyperthyroid patients. Surgery, stress, or illness can precipitate myxedema or thyroid storm in patients with untreated or severe thyroid dysfunction. In general, if a patient has moderate or worse hypothyroidism (i.e., elevated TSH and low free T_4—with or without associated symptoms), elective surgery should be postponed until the individual is euthyroid. Similarly, elective *non-thyroid* surgery should also be delayed to facilitate treatment of patients with overt hyperthyroidism (i.e., suppressed TSH with elevated free T_4 or T_3 concentrations—with or without associated symptoms). Consultation with an endocrinologist is necessary if surgery is urgent in patients with thyroid dysfunction. If surgery is urgent, hyperthyroid patients can be treated with β-adrenergic blockers, antithyroid medications (e.g., methimazole, propylthiouracil, potassium iodide), and corticosteroids. Other potentially useful tests include chest radiography or computed tomography scans to evaluate tracheal or mediastinal involvement by a goiter. All thyroid replacement therapy and antithyroid drugs should be continued on the day of surgery.

Parathyroid Disease

Parathyroid hormone regulates calcium. Most cases of hyperparathyroidism are discovered based on an incidental elevated calcium level found during diagnostic testing. *Primary* hyperparathyroidism is caused by a primary disorder of the parathyroid glands (adenomas or hyperplasia). *Secondary* hyperparathyroidism is parathyroid gland hyperplasia induced by the hyperphosphatemia and hypocalcemia that occur during chronic renal failure. *Tertiary* hyperparathyroidism occurs when the parathyroid hyperplasia in secondary hyperparathyroidism functions autonomously. Hypercalcemia from parathyroid disease is associated with osteoporosis and bone loss. It is very unlikely that parathyroid glands become sufficiently enlarged to compromise the airway. Hypoparathyroidism is very uncommon, but it can be the consequence of a prior total parathyroidectomy.

Hypothalamic-Pituitary-Adrenal Disorders

The hypothalamus releases corticotropin-releasing hormone, which regulates adrenocorticotropic hormone (ACTH) release from the anterior pituitary gland. ACTH, in turn, regulates cortisol release from the adrenal cortex. Cortisol secretion varies with the circadian rhythm, with the highest release in the morning. Additionally, release increases with physical stress, psychological stress, fever, and hypoglycemia. Among physical stressors, surgery is one of the most potent activators of the hypothalamic-pituitary-adrenal axis. Although ACTH concentrations increase with surgical incision and through the surgical procedure, the greatest ACTH secretion occurs during termination of anesthesia and the immediate postoperative period.[280] The magnitude and duration of the cortisol response reflects the degree of physiological stress imposed by the surgical stress. In procedures with minimal associated stress (e.g., inguinal hernia repair), increased cortisol secretion lasts for about 24 hours.[280] In more complicated procedures (e.g., major abdominal surgery), the response is larger in magnitude and lasts for about 5 days after surgery.[280,281]

Excess adrenal hormones result from endogenous cortisol associated with pituitary or adrenal tumors, or exogenous glucocorticoids used to treat disorders such as asthma or inflammatory diseases. Cushing syndrome refers to the combinations and symptoms due to chronic excess glucocorticoid exposure (either endogenous or exogenous). Cushing disease is the specific situation when the excess glucocorticoids are related to an ACTH-producing pituitary tumor. Other causes of Cushing syndrome include exogenous corticosteroids, adrenal tumors, adrenal hyperplasia, and neoplasms that secrete ectopic ACTH. The major manifestations of Cushing syndrome are obesity (with characteristic patterns of fat deposition causing "moon facies" and a "buffalo hump"), diabetes mellitus, female virilization, OSA, hypertension, elevated cardiovascular risk, elevated venous thromboembolism (VTE) risk, osteoporosis, striae, skin atrophy, and easy bruising. Airway management can be challenging in affected patients due to obesity and OSA. In addition, peripheral intravenous access can be difficult because of skin atrophy and obesity. These patients may require an ECG and blood sampling for electrolytes and glucose. Despite easy bruising, they have normal coagulation profiles.

An important issue for patients with chronic corticosteroid exposure is whether perioperative "stress-dose steroids" are needed. Both endogenous and exogenous glucocorticoids exert important negative feedback suppression on the hypothalamic-pituitary-adrenal axis. Thus, chronic exogenous corticosteroid exposure suppresses the adrenals and may blunt the normal cortisol hypersecretion associated with surgery—even if the patient does not demonstrate Cushing syndrome. Perioperative corticosteroid supplementation is needed only when a patient is likely to have suppression of the hypothalamic-pituitary-adrenal axis. Thus, supplementation is not required for individuals who have received less than 5 mg prednisone (or its equivalent) daily,[282] or less than 3 weeks of corticosteroids (regardless of dose).[282] These individuals should simply continue their usual long-term corticosteroid regimen through the perioperative period. Conversely, patients taking prednisone (or its equivalent) in daily doses exceeding 20 mg/day for more than 3 weeks, and patients with Cushing syndrome should have perioperative corticosteroid supplementation. The need for supplementation is unclear for patients who have taken prednisone (or its equivalent) at a daily dose of 5 to 20 mg for more than 3 weeks. The options are to simply empirically provide perioperative corticosteroid supplementation or refer the patient to an endocrinologist for formal evaluation of their hypothalamic-pituitary-adrenal axis. There is no clear consensus on the optimal perioperative corticosteroid supplementation regimen.[284] A proposed regimen that accounts for contemporary evidence and different stress-response profiles across surgical procedures is presented in Table 31.15.[284]

TABLE 31.15 Recommendations for Perioperative Corticosteroid Coverage

Surgical Stress	Target Hydrocortisone Equivalent	Preoperative Corticosteroid Dose	Perioperative Corticosteroid Dose
Superficial procedure (e.g., biopsy, dental procedure)	8–10 mg/day	Usual daily dose	▪ Then usual daily dose
Minor (e.g., inguinal hernia repair, colonoscopy, hand surgery)	50 mg/day	Usual daily dose	▪ Hydrocortisone 50 mg IV before incision ▪ Hydrocortisone 25 mg IV every 8 h for 24 h ▪ Then usual daily dose
Moderate (e.g., colon resection, total joint replacement, lower extremity revascularization)	75–150 mg/day	Usual daily dose	▪ Hydrocortisone 50 mg IV before incision ▪ Hydrocortisone 25 mg IV every 8 h for 24 h ▪ Then usual daily dose
Major (e.g., esophagectomy, pancreatoduodenectomy, major cardiac, major vascular, trauma)	75–150 mg/day	Usual daily dose	▪ Hydrocortisone 100 mg IV before incision ▪ Continuous IV infusion of 200 mg of hydrocortisone over 24 h ▪ Then usual daily dose OR ▪ Hydrocortisone 50 mg IV every 8 h for 24 h ▪ Taper dose by 50% per day until usual daily dose is reached* ▪ Then usual daily dose

*Administer continuous IV fluids with 5% dextrose and 0.2% to 0.45% sodium chloride (based on degree of hypoglycemia).
IV, Intravenous.

Patients with adrenal insufficiency have weakness, weight loss, hypotension, orthostasis, hypovolemia, hyperpigmentation, and electrolyte abnormalities. Adrenal insufficiency results from destruction of the pituitary gland, destruction of the adrenal glands (e.g., autoimmune disease, tuberculosis, HIV infection), or long-term exogenous glucocorticoid administration (most common cause). To help establish the diagnosis and cause of adrenal insufficiency, patients require a morning cortisol concentration measurement, morning plasma ACTH concentration measurement, and often an ACTH stimulation test.[285,286] If the serum cortisol concentration is inappropriately low and a simultaneous plasma ACTH concentration is very high, primary adrenal insufficiency (i.e., primary adrenal disease) is the cause. Secondary (i.e., pituitary disease) or tertiary (i.e., hypothalamic disease) is the diagnosis if both serum cortisol and plasma ACTH concentrations are inappropriately low. Consultation with an endocrinologist is required if formal diagnostic testing for adrenal insufficiency is required, and to facilitate treatment of patients meeting the diagnostic criteria. Patients should continue their replacement corticosteroid therapy on the day of surgery and may need further supplementation based on the expected surgical stress response (see Table 31.15).

Importantly, aldosterone, although also produced by the adrenal cortex, is controlled instead by the renin-angiotensin system, not the hypothalamic-pituitary-adrenal axis. Aldosterone regulates volume and electrolytes (absorption of sodium and chloride; secretion of potassium and hydrogen ions).

Multiple Endocrine Neoplasia Syndromes

Multiple endocrine neoplasia (MEN) syndromes are autosomal dominant inherited disorders. There are three types, namely MEN type 1, MEN type 2A, and MEN type 2B (Box 31.11). Although rare (2 in 100,000 for MEN type 1, and 3 in 100,000 for MEN type 2), recognition is important to facilitate treatment of the affected patient and evaluation of family members. MEN type 1 is characterized by the "3 Ps," namely tumors of the parathyroid glands, anterior pituitary, and pancreatic islet cells. Hyperparathyroidism is the most common manifestation of MEN type 1, with 90% penetrance by the age of 40 years. Affected individuals are also predisposed to other tumors, including gastrinomas (usually in the duodenum), carcinoid tumors (thymus or bronchi), enterochromaffin cell-like gastric tumors, adrenocortical adenomas, and lipomas. Individuals

BOX 31.11 Types of Multiple Endocrine Neoplasia Syndromes

Multiple Endocrine Neoplasia Type 1

1. Primary hyperparathyroidism
2. Entero-pancreatic tumor (e.g., gastrinoma, insulinoma, nonfunctioning)
3. Anterior pituitary tumor (e.g., prolactinoma)
4 Others
   (a). Foregut carcinoid tumor (e.g., thymus, gastric enterochromaffin-like tumor)
   (b). Adrenal cortical tumor (nonfunctioning)
   (c). Lipomas
   (d). Facial angiofibromas
   (e). Collagenomas

Multiple Endocrine Neoplasia Type 2A

1. MEN2A classical syndrome (i.e., medullary thyroid cancer, pheochromocytoma, primary hyperparathyroidism)
2. MEN2A with cutaneous lichen amyloidosis
3. MEN2A with Hirschsprung disease
4. Familial medullary thyroid cancer (no pheochromocytoma or parathyroid hyperplasia)

Multiple Endocrine Neoplasia Type 2B

1. Medullary thyroid cancer
2. Pheochromocytoma
3. Others
   (a). Mucosal neuromas
   (b). Intestinal ganglioneuromas
   (c). Marfanoid habitus

with gastrinomas can develop Zollinger-Ellison syndrome, which is characterized by multiple peptic ulcers due to gastrin hypersecretion. While testing for MEN type 1 gene mutations is possible,[287] there is little evidence that early detection improves the disease prognosis.

Within MEN type 2A, there are four subtypes, namely classical MEN type 2A, MEN type 2A with cutaneous lichen amyloidosis, MEN type 2A with Hirschsprung disease, and familial medullary thyroid cancer (see Box 31.11). Hyperparathyroidism in MEN type 2A is often mild or asymptomatic. Since pheochromocytoma (see section on "Pheochromocytoma") is present in about 50% of MEN type 2 cases, this diagnosis must be considered as a possible component of MEN type 2 syndrome. Furthermore, if a pheochromocytoma is present, it should be removed before any other tumor resections. Extraadrenal pheochromocytoma tumors are rare in MEN type 2, but bilateral adrenal disease is common. It is unusual for pheochromocytoma to precede a medullary thyroid carcinoma or be the initial manifestation of MEN type 2. In contrast to MEN type 1, early diagnosis of MEN type 2 through genetic screening is very important. This genetic testing predicts the clinical disease phenotype (e.g., age of onset, aggressiveness), guides surveillance for associated tumors, and informs timing of prophylactic thyroidectomy to prevent medullary thyroid carcinoma.

Pheochromocytoma

Pheochromocytomas are catecholamine-secreting tumors that arise from chromaffin cells of the adrenal medulla. Similar tumors arising from sympathetic ganglia are termed catecholamine-secreting paragangliomas or extraadrenal pheochromocytomas. Nonetheless, the term "pheochromocytoma" is often used to refer to either type of tumor. These rare tumors (incidence ~1 per 100,000 person-years)[288] occur most commonly between ages 40 and 60 years, with equal incidence in males and females. About 40% of cases occur as part of a familial disorder (i.e., von Hippel-Lindau syndrome, MEN type 2, neurofibromatosis type 1). These tumors tend to present at a younger age and are more likely to be bilateral adrenal pheochromocytomas or paragangliomas.

Pheochromocytomas are usually discovered when patients present with consistent symptoms, suggestive family history, or incidental adrenal mass. About half of patients have symptoms, which are typically paroxysmal. The classic triad of associated symptoms are episodic headaches (90% of symptomatic patients), sweating (60%-70% of symptomatic patients), and tachycardia. About half of patients have paroxysmal hypertension, 5% to 15% have normal blood pressure, and the remainder have what appears to be essential hypertension. Other manifestations include orthostatic hypotension, psychiatric disorders (i.e., panic attacks), pallor, blurred vision, weight loss, hyperglycemia, and cardiomyopathy. A diagnosis of pheochromocytoma should be considered if any of the following features is present.[289]

- Triad of episodic headaches, sweating, and tachycardia
- Hyperadrenergic spells (e.g., nonexertional palpitations, diaphoresis, headache, tremor)
- Hypertension that is difficult to control, or occurs at a young age
- Hypertension associated with new-onset or atypical diabetes mellitus
- Idiopathic dilated cardiomyopathy
- Family history of pheochromocytoma or suspicious familial syndrome (von Hippel-Lindau syndrome, MEN type 2, neurofibromatosis type 1)
- A history of gastric stromal tumors or pulmonary chondromas
- Incidentally discovered adrenal mass

Measurements of fractionated metanephrine and catecholamine concentrations in the urine and plasma generally establish the diagnosis of pheochromocytoma, with recent guidelines focusing on initial testing with either plasma-free metanephrines or urinary fractionated metanephrines.[290] Nonetheless, since testing algorithms vary considerably across hospitals and regions, a referral to an appropriate specialist (e.g., endocrinologist) should be made to facilitate a formal diagnosis in an individual with suspicious findings.

Patients scheduled for pheochromocytoma resection should undergo surgery at centers with experienced teams of anesthesiologists and surgeons. They also require about 10 to 14 days of medical preparation before surgery to mitigate perioperative risks. The overarching goals of this preparation are to control hypertension, control tachycardia, and normalization of intravascular volume status. The mainstay of medical therapy is preoperative α-adrenergic blockade started 7 to 14 days before surgery.[290] The preferred drug at many centers is phenoxybenzamine, which is an irreversible, long-acting, nonspecific α-adrenergic blocking drug. The initial dose is 10 mg once or twice daily, and the dose is increased by 10 to 20 mg every 2 to 3 days as needed. Most patients eventually need doses ranging from 20 to 100 mg daily. The arterial blood pressure target is less than 130/80 mm Hg in the seated position, with systolic pressure less than 90 mm Hg while standing. Typical side effects include orthostatic dizziness, fatigue, and nasal congestion. Given these side effects, as well as higher rates of postoperative hypotension after preoperative phenoxybenzamine treatment, some centers instead use selective α_1-adrenergic blocking drugs (e.g., prazosin, terazosin, doxazosin).[291] These agents are also preferable when long-term pharmacologic treatment is indicated (e.g., metastatic pheochromocytoma). The disadvantage of selective α_1-adrenergic blocking drugs is their incomplete degree of α-adrenergic blockade, thus resulting in more episodes of intraoperative hypertension.[291]

After adequate α-adrenergic blockade, β-adrenergic blockade may be started cautiously with short-acting drugs. As an example, 10 mg of propranolol every 6 hours can be used. After 24 to 48 hours, a long-acting preparation (e.g., metoprolol, atenolol) can be substituted, provided that the patient tolerates β-adrenergic blockade. The dose is then adjusted to achieve a heart rate between 60 and 80 beats/min. β-Adrenergic blockade should *never* be initiated before α-adrenergic blockade.[290] In the setting of unopposed α-adrenergic receptor stimulation, blockade of vasodilatory peripheral β-adrenergic receptors worsen hypertension, while acute depression of cardiac function can precipitate acute heart failure. In addition, initiation of β-adrenergic blockade may unmask a catecholamine-induced cardiomyopathy, with resulting acute pulmonary edema.

Alternatives to perioperative α-adrenergic blockade include calcium channel blockers and metyrosine.[290]

Nicardipine is the most commonly used calcium channel blocker for this indication, with a starting oral dose of 30 mg twice daily (sustained release preparation). The main role for calcium channel blockers is likely to supplement α- and β-adrenergic blockade when blood pressure control is inadequate, or to treat patients with intolerable side effects from usual therapy. Monotherapy with calcium channel blockers is not recommended.[290] Metyrosine, which inhibits catecholamine synthesis, has many side effects (e.g., sedation, diarrhea). As a consequence, it is also reserved for cases where conventional treatment is insufficient or not tolerated.

The preoperative evaluation of a patient with known pheochromocytoma should focus on the cardiovascular system (including orthostatic vital signs) and current medical treatment for pheochromocytoma (including adequacy of treatment). Laboratory testing includes an ECG, as well as blood sampling for a CBC, electrolyte concentrations, creatinine concentrations, and glucose concentrations. The patient may also warrant echocardiography or a cardiology consultation.

KIDNEY DISEASE

During preoperative evaluation, it is important to establish the severity, type, and underlying cause of preoperative renal impairment. Based on the Kidney Disease Improving Global Outcomes (KDIGO) guideline group, CKD is defined as a GFR less than 60 mL/min/1.73 m^2 for at least 3 months, regardless of the underlying cause.[292] Chronic kidney failure is defined as a GFR less than 15 mL/min/1.73 m^2 or the need for renal replacement therapy (i.e., dialysis). End-stage renal disease generally refers to chronic kidney failure that requires either dialysis or transplantation. GFR decreases with age; the renal reserve of a normal 80-year-old person is less than half that of a 40-year-old person. Thus, creatinine concentration is often not an accurate indicator of renal function, especially in older individuals.[293] The GFR can be reduced by 50% without a rise in creatinine concentration, while creatinine concentration does not exceed normal limits until GFR has fallen to less than 50 mL/min. Consequently, it is preferable to estimate renal function using an estimated GFR (eGFR) equation, such as the Cockcroft-Gault,[294] Modification of Diet in Renal Disease,[295] and current CKD-EPI equations.[296] Online calculators to estimate renal function are available (e.g., www.kidney.org/professionals/kdoqi/gfr_calculator). Calculating an eGFR is especially important in patients who are older, have elevated creatinine concentrations, or have other risk factors for CKD.[293] Given the inaccuracy of these equations at lower creatinine concentrations, values of eGFR that are greater than 60 mL/kg/min/1.73 m^2 should simply be reported as ">60 mL/kg/min/1.73 m^2." In the United States, the leading causes of end-stage renal disease are diabetes mellitus and hypertension.

AKI is a sudden decrease in renal function with the possible decrease in urine output. Episodes of AKI can occur in individuals with or without CKD. Several consensus-based criteria for classifying AKI have been developed, including the RIFLE classification scheme,[297] the Acute Kidney Injury Network classification scheme,[298] and the current KDIGO criteria.[299] AKI may be reversible if precipitating factors are identified and corrected. Classifying AKI into prerenal, renal, and postrenal causes allows for a systematic approach. Prerenal causes can often be differentiated by calculating the blood urea nitrogen-to-creatinine ratio. A ratio more than 20 suggests prerenal etiologies, with hypovolemia or hypotension the most common. A fractional excretion of sodium (FENa) less than 1% also suggests prerenal disease (in the absence of concomitant diuretic administration) and can be calculated using the following formula:

$$\text{FENa} = \frac{P_{Cr}/U_{Cr}}{P_{Na}/U_{Na}}$$

Obstruction, which results in dilated ureters and enlarged kidneys, should always be considered in the differential diagnosis of AKI. Prompt identification with ultrasound should lead to attempts to decompress the outflow tract.

Patients with CKD have many associated comorbidities, both related to the underlying diseases that led to CKD and its resulting end-organ complications. Cardiovascular issues include hypertension, IHD, ventricular dysfunction (diastolic and systolic), heart failure, CVD, PAD, pericarditis, pericardial effusions, and valvular heart disease (valvular calcification with resulting regurgitation or stenosis). Pulmonary hypertension and increased cardiac output occur in patients with arteriovenous fistulas. CKD is also associated with chronic anemia due to reduced erythropoietin production by the kidneys. While treatable with erythropoiesis stimulating agents, complete "normalization" of hemoglobin concentration (i.e., 135 g/L vs. 113 g/L) may actually increase morbidity and vascular events.[300] Hence, current KDIGO guidelines recommend using erythropoiesis stimulating agents to treat hemoglobin concentrations less than 90 g/L, but avoid increasing the concentration to above 130 g/L.[301] Other hematological abnormalities include platelet dysfunction and increased bleeding, despite normal platelet counts, prothrombin times, and activated partial thromboplastin time (aPTT). Once dialysis is begun, patients become more prone to hypercoagulable states. Patients with CKD can develop autonomic and peripheral (sensory and motor) neuropathies. Unsurprising, CKD is associated with many electrolyte disturbances. Chronic metabolic acidosis is common, but it is usually mild and compensated for by chronic hyperventilation. Hyperkalemia is the most serious electrolyte disturbance. Hypocalcemia is common in patients undergoing dialysis, although with long-term disease, secondary and tertiary hyperparathyroidism eventually develops. Chronically elevated troponin concentrations are common in end-stage renal disease, which does influence interpretation of any postoperative troponin elevations.[302] Since insulin is metabolized by the kidneys, worsening renal function should be suspected in diabetic patients with end-stage renal disease who develop improved glycemic control or unexpected hypoglycemia.

Preexisting CKD is a risk factor for increased postoperative complications, including cardiac complications,[97] AKI,[303,304] acute stroke,[305] and death.[99] Risk factors for *postoperative* AKI have also been identified. In cardiac surgery, several simple preoperative risk indices have been developed to predict postoperative AKI requiring dialysis.[268,269] Important risk factors in these indices include complex surgery, nonelective surgery, CKD, diabetes mellitus, heart failure, female sex, and COPD. In noncardiac surgery, identified risk factors for AKI include increased age, male sex, symptomatic heart failure, hypertension, liver disease (including ascites), CKD, PAD, COPD, nonelective surgery, and intraperitoneal surgery.[303,304] Preoperative identification of at-risk patients can facilitate care, such as preoperative hydration and avoidance of hypovolemia. Nonsteroidal antiinflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2) inhibitors interfere with renal perfusion autoregulation and should be avoided or discontinued in patients with CKD. In contrast, these drugs do not increase the risk of postoperative AKI in patients with normal renal function.[306] Many drugs are also metabolized or cleared by the kidneys. Drugs with particular perioperative implications are the LMWHs since there is no easy method to monitor their anticoagulation effects. LMWHs are cleared by the kidneys and are not removed during dialysis; thus, they have a prolonged duration of action in patients with CKD. Similarly, dosing of DOACs have to be adjusted in CKD (see Table 31.11).

The preoperative evaluation of patients with CKD should emphasize the cardiovascular system, cerebrovascular system, intravascular volume status, and electrolyte status. The early stages of CKD typically cause no symptoms. The anesthesiologist should inquire about the cardiovascular systems (i.e., chest pain, orthopnea, paroxysmal nocturnal dyspnea), urine output, associated comorbidities, medications, dialysis schedules, and any hemodialysis catheter problems (e.g., infection, thrombosis). Information on the patient's target and current weight may be helpful for assessing volume status. Patients with CKD need an ECG and blood sampling to measure electrolyte, calcium, glucose, albumin, and creatinine concentrations. Further evaluation is needed if the ECG shows LVH (hypertension), peaked T waves (hyperkalemia), flattened T waves, a prolonged PR interval, or a prolonged QT interval (hypokalemia). A chest radiograph (infection, volume overload), echocardiogram (murmurs, heart failure), and cardiology evaluation may be necessary in some cases. Venous access sites or blood draws from the brachial, cephalic (antecubital), and central veins in the nondominant upper extremity should be avoided in patients who may eventually need fistulas in those locations for dialysis.

Preoperative renal replacement therapy (dialysis) schedules should be coordinated with the timing of the planned surgery. Dialysis is important for correct volume overload, hyperkalemia, and acidosis before planned surgery. Ideally, elective surgery should be performed about 24 hours after dialysis. Performance of surgery shortly after dialysis should be avoided, because of the risks of acute volume depletion and electrolyte alterations. Specifically, dialysis leads to fluid shifts and electrolyte (i.e., sodium, potassium, magnesium, phosphate) imbalance, especially related to shifting of electrolytes between intracellular and extracellular compartments.

Contrast-Induced Nephropathy

Contrast-induced nephropathy is defined as AKI that occurs after radiocontrast administration. Typically, the creatinine concentration increases within 24 to 48 hours after contrast exposure, after which it typically declines to baseline levels within 3 to 7 days. Recent (<24 hours) preoperative contrast exposure is also a risk factor for AKI following cardiac surgery.[307] Even when renal function returns to normal, patients with contrast-induced nephropathy experience elevated risks of short-term and long-term mortality.[308] Risk factors for contrast-induced nephropathy are CKD (especially diabetic nephropathy), heart failure, hypovolemia, and certain contrast exposure characteristics (i.e., high volume, ionic agents, hyperosmolal agents). Preventative strategies include avoiding volume depletion, discontinuing NSAIDs for 24 to 48 hours, using a low-risk contrast administration protocol (i.e., low volume of a low-osmolal or iso-osmolal agent), and periprocedure intravenous volume administration with normal saline. Despite initial promising results for N-acetylcysteine and sodium bicarbonate in relatively small randomized trials, a large trial with more than 5000 high-risk participants found that neither approach prevented contrast-induced nephropathy.[309]

HEPATIC DISORDERS

Liver disease can affect the hepatocytes and/or biliary system, thereby impacting protein synthesis (e.g., coagulation factors, albumin), bile regulation, and metabolism of drugs or toxins. Hepatocellular diseases, such as hepatitis (viral, alcoholic, autoimmune hepatitis) and hepatocellular carcinoma, affect hepatocytes and liver synthetic function. Obstructive disorders, including choledocholithiasis, bile duct tumors (extrahepatic), primary biliary cirrhosis (intrahepatic), and primary sclerosing cholangitis (extrahepatic and intrahepatic), cause bile stasis. Most drug-induced liver disease, as well as some forms of viral hepatitis, affect both hepatocytes and the biliary system.

The preoperative history typically reveals the underlying disease etiology, disease severity, therapies, and associated complications. Some patients with liver disease may be asymptomatic, whereas others may complain of fatigue, weight loss, dark urine, pale stools, pruritus, right upper quadrant pain, bloating, and jaundice. The physical examination should assess for weight, vital signs (including oxygen saturation), jaundice, bruising, ascites, pleural effusions, peripheral edema, hepatomegaly, splenomegaly, and altered mental status. The presence of encephalopathy, coagulopathy, ascites, volume overload, and infection should be determined before surgery. The bilirubin concentration generally must exceed 25 g/L before icterus is evident in mucous membranes and sclerae. If new-onset or worsening encephalopathy is identified, precipitating factors should be sought, such as infection, drug effects, bleeding, or electrolyte disturbances.

Baseline testing includes an ECG and blood sampling for CBC, electrolyte concentration, creatinine concentration, liver function tests, albumin concentration, and INR. Patients suspected of having hepatitis may require screening for the hepatitis A immunoglobulin M (IgM) antibody, the hepatitis B surface and core antigens, the hepatitis B surface antibody, and the hepatitis C antibody. A chest radiograph can help identify any suspected effusions. Coagulopathy can be a result of vitamin K deficiency (from cholestasis), factor deficiency (from loss of synthetic function), or thrombocytopenia (from splenomegaly and portal hypertension). Thus, therapy to correct coagulopathy should be directed at the cause. Vitamin K, fresh frozen plasma, or platelets may correct deficiencies. Vitamin K, taken at 1 to 5 mg orally or subcutaneously daily for 1 to 3 days, may correct a prolonged PT and carries minimal risk. The coagulopathy in patients with synthetic failure is not likely to correct, thus necessitating fresh frozen plasma transfusion aiming for an INR less than 1.5. Limited evidence suggests that lactulose (30 mL orally every 6 hours for 3 days preoperatively) with the last dose within 12 hours of surgery, or oral bile salts with intravenous hydration beginning the night before the operation, may reduce perioperative AKI in patients at risk.[310] Reduction of ascites preoperatively may decrease the risk of wound dehiscence and improve pulmonary function. Sodium restriction (in diet and intravenous solutions), diuretics (especially spironolactone), and paracentesis are useful for reducing ascites. If ascites fluid is aspirated, it should also be analyzed for infection. Encephalopathy is frequently precipitated by an additional acute insult such as infection, gastrointestinal bleeding, hypovolemia, or sedatives. It is therefore important to determine reversible factors and treat them accordingly. Lactulose (30 mL every 6 hours orally) is first-line therapy. Addressing nutritional deficiencies with enteral or parenteral supplementation may have benefits, especially in alcoholic patients. Patients who abuse alcohol may be at risk for neurologic deterioration (i.e., Wernicke-Korsakoff syndrome) if thiamine, folate, and vitamin B_{12} supplements are not provided, especially when these patients are given nutrition or glucose. These same patients are also at risk of alcohol withdrawal syndromes.

The perioperative risk of patients with chronic hepatitis or cirrhosis is predicted by histologic severity, portal hypertension, and impairment of liver function. Patients with severe liver disease have increased perioperative morbidity and mortality; common adverse events are bleeding, infection, liver failure, and hepatorenal syndrome. Predictors of poor perioperative outcome in patients with liver disease include the following:

- Child-Turcotte-Pugh class C cirrhosis, which is calculated using bilirubin concentration, albumin concentration, PT, ascites severity, and encephalopathy severity (Table 31.16)
- Model for end-stage liver disease (MELD)[311] score of 15 or more (the MELD score is calculated using serum bilirubin concentration, INR, and serum creatinine concentrations)
- Acute hepatitis (viral or alcoholic)
- Chronic active hepatitis with jaundice, encephalopathy, coagulopathy, or elevated liver enzymes
- Abdominal surgical procedures
- PT prolongation of 3 seconds or more that is refractive to vitamin K therapy

TABLE 31.16 Child-Turcotte-Pugh Classification

Parameter	1 point	2 points	3 points
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–2.5	<2.8
Prothrombin time (seconds over control)	<4	4–6	>6
Encephalopathy	None	Grade 1–2	Grade 3–4

Class A: <7 points.
Class B: 7-9 points.
Class C: >9 points.

The MELD score can be calculated as shown below (where creatinine and bilirubin concentrations are expressed in mg/dL):

$$\begin{aligned}\text{MELD} = 6.43 &+ [3.78 \times \log_e(\text{bilirubin})] \\ &+ [11.2 \times \log_e(\text{INR})] + [9.57 \times \log_e(\text{creatinine})]\end{aligned}$$

Online calculators are also available to calculate MELD scores readily (e.g., www.unos.org). In some cases, it may be appropriate to delay elective surgery until an acute episode of hepatitis (or exacerbation of chronic disease) has resolved, or until a diagnosis is established for newly discovered hepatic dysfunction. Elective surgery is contraindicated in patients with acute or fulminant liver disease. High-risk patients are best managed collaboratively with a liver specialist.

Hepatitis

Hepatitis, which is defined as hepatocyte inflammation, can be caused by drugs, alcohol, viruses (hepatitis A, B, C, D, and E), and autoimmune diseases (see also Chapter 16). These disorders generally have an initial acute phase, as well as a subsequent chronic phase that can progress to cirrhosis. Risk factors for hepatitis are alcohol use, sexual activity (i.e., multiple partners, sex industry workers, sex with sex industry workers, men who have sex with men), intravenous drug use, blood transfusions before 1992, obesity (i.e., nonalcoholic steatohepatitis [NASH]), tattoos, body piercing, and travel to developing countries. Hepatitis A is caused by contaminated food, contaminated water, or contact with an infected person. Since it rarely progresses beyond the acute illness, a remote history of hepatitis A has no perioperative significance. Hepatitis B is transmitted by sexual activity or contact with blood (rarely after implementation of screening in 1986). It varies in severity and can advance to cirrhosis; this has become much less common due to widespread hepatitis B vaccination. Additionally, antiviral therapy can treat the infection, albeit with variable efficacy. Hepatitis C is transmitted primarily through blood exposure (all blood has been screened since 1992), especially among intravenous drug users. Many patients are unaware of infection because the acute phase is often asymptomatic. While hepatitis C infection can advance to cirrhosis, currently available antiviral therapy can now eliminate infection in almost all patients. Hepatitis D occurs only in conjunction with hepatitis B infection, whereas hepatitis E is less common in high-income countries. Hepatitis D can progress to cirrhosis, while hepatitis E rarely progresses beyond the acute illness. Alcoholic hepatitis generally occurs after at least 20 years of moderate to heavy daily alcohol intake (>100 g/day) and may progress to cirrhosis. Autoimmune hepatitis primarily affects young females and has an as yet unknown etiology. Many different drugs (including herbal and over-the-counter preparations) can also cause hepatitis, with examples being statins, isoniazid, and acetaminophen.

Obstructive Jaundice

Extrahepatic bile duct obstruction may be caused by gallstones, tumors (e.g., pancreatic, gallbladder, bile duct, ampulla of Vater), or scarring. Patients can present with jaundice, pruritus, and abdominal pain. Risk factors for postoperative mortality in these patients include a hemoglobin concentration less than 100 g/L, serum bilirubin exceeding 20 mg/dL, and serum albumin lower than 25 g/L.[312] These patients are at elevated risk for postoperative AKI, which may be prevented using bile salts or lactulose.[310]

Miscellaneous Liver Diseases

Wilson disease, hemochromatosis, and α_1-antitrypsin deficiency are uncommon hereditary causes of liver disease. All three conditions can eventually lead to end-stage liver disease. In contrast, another hereditary liver disease, Gilbert disease, is characterized by a mildly elevated bilirubin level and no perioperative significance. NASH, also known as “fatty liver,” progresses to liver fibrosis, cirrhosis, and end-stage liver disease (sometimes necessitating liver transplantation). The condition is associated with obesity, hypertension, dyslipidemia, and diabetes mellitus. Following a more than doubling in disease prevalence over the past two decades in the United States,[313] NASH is now the most common cause of chronic liver disease and the second most common indication for liver transplantation.[314,315] Primary biliary cirrhosis (or primary biliary cholangitis) is an autoimmune disorder characterized by intrahepatic biliary obstruction and antimitochondrial antibodies. Affected patients are predominantly female (>90%), may have other autoimmune disorders (e.g., Sjögren syndrome, autoimmune thyroid disease, limited cutaneous scleroderma, rheumatoid arthritis), and can progress to end-stage liver disease. Primary sclerosing cholangitis is characterized by bile duct destruction that can progress to cirrhosis and end-stage liver disease. The disease mainly affects males and may be idiopathic or associated with inflammatory bowel disease (i.e., ulcerative colitis, Crohn disease).

Unexpected Elevated Liver Function Tests

Elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST) concentration reflect hepatocyte damage. Bilirubin concentration measures the liver’s ability to conjugate and excrete bile salts. Alkaline phosphatase (ALP) rises with impaired hepatic excretion, whereas albumin and INR measure the synthetic function of the liver. Routine preoperative laboratory screening may identify about 1 in 700 surgical patients as having unexpected liver diseases, most of which are not severe.[316] Nonetheless, if abnormal liver function test values are unexpectedly found, further testing or referral may be necessary in some cases. Elevated AST or ALT concentrations should prompt hepatitis screening with hepatitis A IgM antibody, hepatitis B antigens (surface and core), hepatitis B surface antibody, and hepatitis C antibody. Elevated concentrations of ALP or bilirubin, especially in association with normal or mild to moderate increased transaminase levels, may indicate obstruction in the biliary system. In these cases, abdominal ultrasound, computed tomography scans, or endoscopic retrograde cholangiopancreatography may establish a diagnosis.

Cirrhosis

Cirrhosis is defined as irreversible liver fibrosis and is the end result of most hepatotoxic conditions. This fibrosis leads to portal hypertension, impaired synthetic function (i.e., synthesis of proteins such as clotting factors), and impaired metabolic functions (i.e., clearance of toxins and drugs). Portal hypertension can lead to splenomegaly, esophageal varices, ascites, dependent edema, and pleural effusions. Patients with ascites may also develop spontaneous bacterial peritonitis, which is associated with increased perioperative mortality. Other complications include hepatic encephalopathy, bleeding, thrombocytopenia, low albumin concentrations, and prolonged INR. Hepatopulmonary syndrome may develop, resulting in hypoxemia and pulmonary hypertension because of pulmonary shunts. Jaundiced patients in particular are at risk for developing hepatorenal syndrome, which is renal insufficiency associated with hepatic disease but without any primary renal disease. The condition may be related to renal hypoperfusion. Patients with end-stage liver disease also develop a high–cardiac output state, characterized by decreased systemic vascular resistance. The Child-Turcotte-Pugh classification can predict perioperative morbidity and mortality, with especially high risks in patients assigned to class C (see Table 31.16). The MELD score also predicts perioperative risks, perhaps better than the Child-Turcotte-Pugh classification,[317] with scores exceeding 14 indicative of increased perioperative risk.

HEMATOLOGIC DISORDERS

Anemia

Anemia is a very common preoperative hematologic disorder with multifactorial etiology. It is strictly defined as a reduced number of circulating red blood cells (RBCs), however, more commonly it is defined based on the value of reduced hemoglobin concentration or reduced hematocrit. For example, the World Health Organization defines anemia as a hemoglobin level less than 130 g/L in adult men and less than 120 g/L in adult women. Anemia can be classified based on the underlying mechanisms as being related to decreased RBC production (e.g., bone marrow disorders, nutritional deficiencies), increased RBC destruction (e.g., hemolytic anemia, intravascular hemolysis), and blood loss (e.g., gastrointestinal blood loss). Anemia may also be classified morphologically based on the associated RBC size, which is itself characterized by the mean corpuscular volume (MCV). Based on this approach, anemia can be classified as microcytic (MCV < 80 femtoliter [fL]), macrocytic (MCV > 100 fL), or normocytic (MCV between 80 and 100 fL). Common causes of microcytic anemia are iron deficiency (including chronic blood loss), thalassemia minor, and anemia associated with inflammatory disease. Common causes of macrocytic anemia include alcoholism, liver disease, hypothyroidism, and vitamin B_{12} deficiency. Common causes of normocytic anemia are CKD, heart failure, and cancer.

Preexisting anemia is a consistently recognized risk factor for postoperative death and complications, including AKI, stroke, and infections.[318] Furthermore, this risk is proportional to the degree of anemia and independent of the patient's other comorbidities.[101,102,319] Nonetheless, there are some important caveats for consideration. First, it remains unclear whether anemia is the causal mechanism for these complications, or instead simply a marker of a high-risk patient. The limited available perioperative data generally suggest that anemia treatment strategies (e.g., erythropoiesis-stimulating agents) can improve hemoglobin concentrations and reduce transfusion requirements, but without convincing evidence for the prevention of death or complications.[320-322] These perioperative data are also generally consistent with findings in nonsurgical populations, such as patients with heart failure.[323-327] Second, there is no consistent hemoglobin concentration threshold that defines elevated perioperative risk. While data from noncardiac surgery performed in Jehovah's Witness patients suggest that risk increases substantially once preoperative hemoglobin concentrations fall below 100 g/L (especially in the presence of concomitant IHD),[328] simply increasing hemoglobin concentrations to this threshold with RBC transfusion is not consistently beneficial. Importantly, transfusion itself has also been associated with poor outcomes in observational studies.[329] In a multicenter randomized trial of 2016 patients undergoing hip fracture surgery, a strategy of transfusing in response to a 100 g/L threshold in hemoglobin concentration was not superior to a strategy of transfusing in response to a 80 g/L threshold or symptoms of anemia.[330] Similarly, in a multicenter randomized trial of 5243 patients undergoing cardiac surgery, a strategy of transfusing in response to a 75 g/L threshold was noninferior to a strategy of transfusing in response to a 95 g/L threshold.[331] These data suggest that the optimal perioperative hemoglobin concentration threshold varies between 75 g/L and 100 g/L across individuals, with interindividual differences largely explained by comorbid conditions (e.g., cardiopulmonary disease).

During the preoperative evaluation of known or suspected anemia, the overarching goals are to determine its etiology, duration, stability, related symptoms, and therapy. Thus, it is important to inquire about any history of anemia (including family history of anemia), colon cancer, gastrointestinal bleeding, genitourinary bleeding, menorrhagia, chronic infections, inflammatory diseases, nutritional deficiencies, and prior weight reduction procedures (e.g., bariatric surgery). The anesthesiologist should also consider the type of surgical procedure, anticipated blood loss, and comorbid conditions that may either affect oxygen delivery or be affected by decreased oxygen delivery (i.e., pulmonary, renal, hepatic, cerebrovascular, cardiovascular disease). In addition, an accurate determination of the patient's medications is helpful, especially because anemia has implications for the risk-to-benefit profile of some perioperative medications, such as β-adrenergic blockers.[103,104]

Patients with anemia or suspected anemia must have a CBC. In general, collaboration with a primary care physician or hematologist is helpful for further evaluation of newly diagnosed anemia. Usual initial studies include peripheral smear and MCV; subsequent studies, such as iron studies (i.e., ferritin, transferrin saturation), vitamin B_{12}, or folate levels, are guided by findings on the smear and the MCV.[332] The MCV is high and the vitamin B_{12} or folate levels are low in macrocytic anemia associated with these deficiencies. Low values in MCV, ferritin (<30 g/μL), and transferrin saturation (<20%) are indicative of iron deficiency anemia. In some cases of iron deficiency anemia, transferrin saturation may still be low (<20%) but ferritin concentrations are in an indeterminate zone (i.e., 30-100 g/μL). Conversely, ferritin and transferrin saturation are normal or high in anemia associated with chronic disease.

Blood type and screening may be necessary based on the level of preoperative anemia and anticipated degree of surgical blood loss. Elective procedures should be postponed in patients with significant anemia, regardless of the anticipated surgical blood loss. This delay allows for evaluation of the underlying cause, such as occult blood loss, vitamin deficiency, or undiagnosed chronic conditions (e.g., CKD). When delay in elective surgery is possible, updated 2015 guidelines from the ASA suggest preoperative treatment with an erythropoiesis-stimulating agent and iron in some patient subgroups (e.g., CKD, anemia of chronic disease, patient's refusal to receive blood transfusions), especially for anemic individuals scheduled for procedures with significant expected blood loss.[333] Similarly, preoperative iron therapy may be considered in patients with known iron deficiency anemia, when time permits.[333]

Sickle Cell Disease

Sickle cell disease is a hereditary hemoglobinopathy with associated vasoocclusive episodes that are responsible for most associated complications. Patients homozygous for hemoglobin S (HbS) have symptomatic disease; they are at risk for major morbidity and have a shortened life expectancy. Patients with SC disease, who have both HbS and HbC, have a much less severe clinical course with moderate anemia. Heterozygous patients (HbS and HbA) have sickle cell trait and rarely have any related consequences. Preoperative assessment should focus on evidence of organ dysfunction and recent patterns of acute exacerbations.[334] Patients may have CKD, loss of renal concentration ability (and therefore are prone to dehydration), splenomegaly, pulmonary hypertension, pulmonary infarctions, CVD, and heart failure. They are at risk for infections because of splenic infarctions. Predictors of perioperative vasoocclusive complications include recent increases in hospitalizations, advanced age, preexisting infections, and pulmonary disease.[334]

The preoperative examination focuses on the frequency, severity, and pattern of vasoocclusive crises. In addition, the anesthesiologist should evaluate the degree of pulmonary, cardiac, renal, and central nervous system damage. Useful tests include an ECG, chest radiograph, and blood sampling for CBC and creatinine concentration. Additional testing (e.g., echocardiogram, arterial blood gases) may be needed. Preoperative prophylactic transfusion is increasingly used in patients with sickle cell anemia who are undergoing any surgical procedure—other than short minor procedures (e.g., biopsy, myringotomy).[335] The objective of any red cell transfusion is to reduce the proportion of abnormal hemoglobin in the affected patient. A prior randomized trial found that prophylactic transfusion to a hemoglobin concentration greater than 100 g/L resulted in fewer adverse events following intermediate-risk surgery.[336] This simpler approach of transfusing to a hemoglobin concentration threshold (>100 g/L) is as effective as a more aggressive approach of transfusing to decrease

HbS concentration to under 30% (while also increasing hemoglobin concentration to ≥ 100 g/L)[337] in the setting of intermediate-risk surgery. It is likely that a more aggressive strategy (i.e., decreasing HbS concentration to < 30%) is preferable for high-risk surgery such as major cardiovascular or intracranial procedures. In general, the decision to transfuse preoperatively should be made only in concert with a hematologist familiar with the disease. Additionally, if the person with sickle cell is managed by a specialist sickle cell service, it is best to liaise with this team before surgery. The patient's surgical admission should be planned to minimize preoperative dehydration (e.g., minimize fasting period, schedule procedure as an early morning case).

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase deficiency is a hereditary Coombs-positive hemolytic anemia. Since it is an X-linked hereditary condition, affected individuals are typically males. Hemolysis may be triggered by drugs (e.g., antipyretics, nitrates, sulfonamides), food (e.g., fava beans), infection, hypoxia, hypothermia, or blood products. Lists of potentially triggering medications are available online (e.g., www.g6pd.org, www.g6pddeficiency.org). The severity of the hemolysis varies across individuals and the underlying genetic defects. Treatment involves avoidance of triggers, folic acid supplementation, and management of acute hemolytic episodes (i.e., hydration, red cell transfusion for severe anemia). The preoperative evaluation should focus on previous hemolysis episodes, predisposing factors, and current hematocrit.

Coagulopathies

Hypocoagulable states may be either inherited (e.g., hemophilia) or acquired (e.g., liver disease, malnutrition, drug exposure). To determine the diagnosis and associated bleeding risk, the anesthesiologist should inquire about known diagnoses, tests, treatments, previous bleeding episodes, and family history. A history of excessive bruising, prolonged bleeding after cuts, heavy menstrual cycles, and bleeding gums is sensitive but not specific. A *change* in these symptoms is likely more meaningful than a long-term history (because what one individual considers excessive may actually be normal). Excessive bleeding after previous procedures or childbirth (especially if transfusions were unexpectedly required) is more definitive but not diagnostic. Petechiae, multiple bruises, hematomas, jaundice, and frank bleeding are important findings. Diagnostic testing may include a CBC (including platelet count), INR, and aPTT; however, *routine* preoperative screening for coagulopathies is not indicated. Clinical indications include a known bleeding disorder, hepatic disease, and anticoagulant use.[5] National guidelines in the United Kingdom also recommend coagulation testing only in patients who are (1) ASA physical status class III or IV; (2) undergoing intermediate, major, or complex surgical procedures; and (3) known to take anticoagulant medications or have chronic liver disease.[274] If a specific cause of bleeding is suspected or known (e.g., liver disease, malnutrition), then additional targeted testing (e.g., liver function tests, protein, albumin) may be needed.

Patients may occasionally have abnormal INR or aPTT results on preoperative screening bloodwork. In patients without a history of vitamin K antagonist use, the most common causes of a prolonged INR are laboratory error, liver disease, and malnutrition. Consequently, the test should initially be repeated. If the repeat test result remains abnormal, both liver function tests and a hepatitis panel are warranted, with possible referral to a hematologist. A trial of oral vitamin K (1-5 mg daily for 3 days) can also be implemented. A prolonged aPTT can result from both hypocoagulable and hypercoagulable (e.g., factor V Leiden, anticardiolipin antibody, lupus anticoagulant, antiphospholipid antibody syndrome) conditions. The first steps are to repeat the test and ascertain possible exposure to heparin. Even small amounts of heparin in indwelling catheters can prolong the aPTT, especially if the blood is drawn from that site. Other than heparin exposure, other causes of a prolonged aPTT include von Willebrand disease (vWD; see section on von Willebrand Disease) and hemophilias (see section on "Hemophilias"). Mixing studies (in which normal blood is mixed with the subject's blood) allows for differentiation between factor deficiencies (aPTT will be corrected) versus inhibitors (no correction). Elective surgical procedures should be postponed until the etiology of abnormal tests is determined and corrections are made.

Hemophilias. Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are X-linked recessive inherited disorders that almost exclusively manifest in males. Hemophilia B is also referred to as "Christmas disease." Hemophilia C is an autosomal recessive deficiency of factor XI (also called Rosenthal syndrome) that tends to affect individuals of Ashkenazi Jewish descent. Hemophilia A has a six-fold higher incidence than Hemophilia B (1 in 5000 male births vs. 1 in 30,000 male births). The severity of bleeding varies across individuals but is similar among relatives (who have the same underlying genetic mutation) and is directly related to the degree of factor deficiency. Severe hemophilia is characterized by less than 1% factor activity, moderate hemophilia by 1% to 5% activity, and mild hemophilia by more than 5% to under 40% activity. Increased disease severity is characterized by an early onset of bleeding episodes, as well as higher risks of both severe and spontaneous bleeding. About two thirds of hemophilia A cases are severe, while the proportion is 50% for hemophilia B. Patients with hemophilia have a prolonged aPTT, but a normal INR and platelet count.

A hematologist must be involved in the perioperative care of patients with hemophilia. A detailed plan to both measure and replace deficient factors is paramount. Current guidelines recommend that, in the setting of major surgery, factor replacement be used to increase preoperative levels to 80% to 100% for hemophilia A and 60% to 80% for hemophilia B.[338] After surgery, the target factor level is 50%, until the surgical wound is healed. The specific required dose of recombinant factor is informed by the targeted increase in factor levels, clinical expertise of the consulting hematologist, individual patient-level factors (e.g., history of previous bleeding episodes), and hospital protocols. The dose required to increase factor VIII levels is:

$$\begin{aligned}\text{Factor VIII dose} &= \text{weight (kg)} \times 0.5\\ &\quad \times (\text{desired absolute \% increase in factor levels})\end{aligned}$$

The typical required dose for factor IX replacement is:

$$\text{Factor IX dose} = \text{weight (kg)} \times (\text{desired absolute \% increase in factor levels})$$

To rapidly increase factor levels to close to 100%, the usual dose required is 50 units/kg for factor VIII and 100 to 120 units/kg for factor IX.[339] Intramuscular injections are to be avoided in these patients.

von Willebrand Disease. vWD is an inherited disorder of von Willebrand factor (vWF) that affects both sexes. It is the most common congenital coagulopathy, occurring in approximately 1% of individuals.[340] Several types (1, 2A, 2B, 2M, 2N) are autosomal dominant, while type 3 is autosomal recessive (Table 31.17). vWD can result from both quantitative and qualitative vWF deficiencies. Most affected patients have a normal INR and platelet count (although type 2B can have a mild thrombocytopenia), but typically elevated aPTT (although patients with mild disease may have normal aPTT). Indeed, vWD is the most common cause of a prolonged aPTT in patients not taking heparin. The condition is diagnosed by measuring plasma vWF functional activity (ristocetin cofactor, which causes platelet aggregation), plasma vWF antigen levels, and factor VIII levels. Most patients with vWD have a history of bleeding, but some do not receive a diagnosis until a challenge to coagulation occurs with major surgery or antiplatelet drug exposure (e.g., aspirin, NSAIDs).

A hematologist should be involved in the care of patients with vWD. Treatment options for vWD include desmopressin acetate (1-desamino-8-d-arginine vasopressin [DDAVP]) and vWF replacement therapy. DDAVP increases the release of factor VIII, vWF, and plasminogen activator from endothelial cells. It is contraindicated in patients with type 2B disease because it increases abnormal vWF release and may cause thrombocytopenia. In addition, it is not recommended in patients with type 3 disease (since there is minimal to no vWF available to be released from endothelial cells). In other cases, an intravenous dose of 0.3 μg/kg (given over 15-30 minutes to minimize hypotension, flushing, and tachycardia) typically raises vWF concentrations by three- to four-fold. Nonetheless, considerable variation in response exists among individuals. Hence, an initial test of DDAVP should be conducted prior to any bleeding episodes (e.g., surgery), while monitoring changes in vWF and factor VIII concentrations over the 4 hours after drug administration. DDAVP is also available as a nasal spray (150 μg for individuals under 50 kg, and 300 μg for individuals weighing 50 kg or more). For individuals who cannot be treated adequately with DDAVP, vWF preparations should be used instead. A variety of preparations are available, including vWF-containing factor VIII concentrates, purified vWF concentrates, and recombinant vWF products. These options, if available, are preferable to cryoprecipitate (which can be used nonetheless, but is associated with higher risks of viral transmission).

Thrombocytopenia. Thrombocytopenia is defined as a platelet count less than 150,000/mm^3. It may be the result of decreased production, increased destruction, or sequestration. Causes include malignant diseases, primary immune thrombocytopenia (ITP), drug-induced thrombocytopenia (e.g., quinine, sulfonamides, ampicillin), rheumatological autoimmune disorders (e.g., SLE, rheumatoid arthritis), pregnancy (i.e., gestational thrombocytopenia, preeclampsia), chronic liver disease (i.e., hypersplenism), alcohol, nutritional deficiencies, infection (e.g., hepatitis C, sepsis), hereditary disease, and disseminated intravascular coagulation. If a patient has an unexpectedly low platelet count, the initial steps are to repeat the test, examine the peripheral smear, and collect blood for the platelet count in a tube without ethylenediaminetetraacetic acid. This chemical is a chelating agent often used to prevent clotting in tubes used for determining CBC, but it can also cause clumping of platelets (termed pseudothrombocytopenia). ITP is a chronic autoimmune disorder characterized by autoantibodies that cause platelet destruction. Usual treatment includes corticosteroids, splenectomy (eliminates the major site of platelet removal), and intravenous immunoglobulin. Patients with ITP often have less bleeding than expected, even at very low platelet levels, likely because of increased platelet turnover with a resulting predominance of young platelets. A patient with newly discovered thrombocytopenia may require a hematology consultation before elective surgery.

Thrombocytopenia within the context of recent heparin exposure should raise a concern regarding potential heparin-induced thrombocytopenia (HIT), which generally occurs within 5 to 10 days after heparin exposure.[341] HIT is an immune-mediated disorder characterized by antibodies directed against platelet factor 4 complexed with heparin. While HIT is characterized by thrombocytopenia, affected patients are at risk for arterial thromboses,

TABLE 31.17 Classification of von Willebrand Disease

Type	Characteristics	Initial Treatment
1	80% of cases; quantitative defect	Desmopressin*
2A	Quantitative and qualitative defect	Desmopressin*
2B**	Rare; quantitative and qualitative defect, autosomal dominant	Cryoprecipitate or factor VIII concentrates with vWF
2M	Qualitative defect	Desmopressin*
2N	Qualitative defect; vWF levels normal; factor VIII reduced	Desmopressin* effect may be too short-lived
3	Rare; low to undetectable levels of vWF	Desmopressin* usually not effective

*Desmopressin acetate (DDAVP).
**With type 2B desmopressin acetate may cause thrombocytopenia. If desmopressin is not effective, factor VIII concentrates containing vWF may be used.
vWF, von Willebrand factor.

venous thromboses, stroke, skin necrosis, limb gangrene, and organ infarction. Since the results of definitive laboratory testing for HIT antibodies (i.e., immunoassay and/or functional assay for HIT antibodies) typically takes several days, the initial presumptive diagnosis is based on clinical presentation and available laboratory tests (e.g., decreasing platelet counts). This initial diagnosis can be aided with validated clinical prediction tools, such as the "4 Ts" score.[342] While waiting for the results of antibody testing in patients with suspected HIT, any heparin therapy (including LMWH) should be immediately discontinued and alternative anticoagulation therapy (e.g., danaparoid, argatroban, bivalirudin, fondaparinux, DOACs) instituted.

In otherwise healthy individuals (i.e., no other basis for elevated bleeding risks) neuraxial anesthesia is generally considered safe once the platelet count exceeds 50,000 to 80,000 per mm^3.[343-346] Surgery can be safely performed in patients with platelet counts higher than 50,000/mm^3.[346] The risk of bleeding increases progressively as the count falls further, to less than 50,000/mm^3. When platelet transfusions are used to treat thrombocytopenia, the platelet count generally rises by 10,000/mm^3 for every unit transfused.

Thrombocytosis. Thrombocytosis is a platelet count more than 450,000/mm^3. It may be physiologic (i.e., exercise, pregnancy), primary (e.g., myeloproliferative disorder), or secondary (e.g., iron deficiency, neoplasm, surgery, chronic inflammation). Increasing levels of thrombocytosis can increase risks for thrombotic events, such as strokes, myocardial infarction, pulmonary emboli, mesenteric emboli, and venous clots. Conversely, patients with primary thrombocytosis (also known as essential thrombocythemia) also have a tendency toward increased bleeding, which may be due to qualitative alterations in platelet function and an acquired von Willebrand syndrome associated with very high platelet counts (>1,000,000/mm^3). Treatments include medications (e.g., hydroxyurea, anagrelide, pegylated interferon) that decrease platelet production and thereby reduce platelet counts over 7 to 10 days. Plasmapheresis, which removes platelets from the circulation, can be used if an immediate lowering in platelet count is required. In cases of secondary thrombocytosis, treatment of the underlying disorder usually results in normalization of the platelet count.

Polycythemia. Polycythemia is characterized by an increased number of circulating RBCs and increased hemoglobin concentration. It can be defined based on hematocrit (>48% in females and >49% in males) and hemoglobin concentration (>160 g/L in females and > 165 g/L in males). Polycythemia can be a primary disorder (i.e., polycythemia vera) or secondary to conditions typically associated with chronic hypoxia (e.g., COPD, high altitude, cyanotic congenital heart disease). A steep increase in blood viscosity occurs once the hematocrit increases to more than 50%, resulting in an increased thrombogenic risk. High hematocrits are associated with increased atherosclerosis (e.g., carotid stenosis, stroke) and cardiac disease (e.g., heart failure, myocardial infarction). Reports on whether polycythemia increases perioperative risk are contradictory. For example, a hematocrit more than 51% was associated with increased postoperative mortality in a retrospective cohort study of more than 310,000 patients.[102] Conversely, a previous smaller study of 200 patients did not find an increased rate of perioperative complications in individuals with secondary polycythemia.[347]

The preoperative evaluation should focus on the pulmonary and cardiovascular systems. On physical examination, the anesthesiologist should examine for cyanosis, clubbing, wheezing, murmurs, and oxygen saturation (via pulse oximetry). Useful laboratory tests include an ECG, arterial blood gases, and chest radiograph. An unexpected finding of polycythemia should prompt an investigation for possible causes, which if not readily apparent, should raise the possibility of polycythemia vera. In such cases, elective surgery should be postponed pending a consultation by a hematologist.

Venous Thromboembolic Disorders. VTE is an important potential risk in hospitalized patients, including surgical patients.[348] Primary VTE prophylaxis is beyond the scope of this chapter and is covered extensively in specialty society practice guidelines.[11,12] Nonetheless, patients should be stratified preoperatively for their risks of perioperative VTE to inform the appropriate selection of prophylactic measures. The expected risk of postoperative VTE depends on both patient-related (e.g., inflammatory bowel disease, acute illness, smoking, malignant disease, obesity, increased age, prior VTE, estrogen use, hypercoagulable state, inherited thrombophilia) and procedure-related (e.g., invasiveness, trauma, immobilization) factors. A reasonable approach for estimating perioperative VTE risk is to use a validated clinical prediction index, a widely used example being the Modified Caprini Risk Assessment Model (Box 31.12).[11,349] A Caprini score of zero indicates very low VTE risk (0.5% risk in the absence of thromboprophylaxis), scores of 1 to 2 indicate low VTE risk (1.5% risk in the absence of thromboprophylaxis), scores of 3 to 4 indicate moderate VTE risk (3.0% risk in the absence of thromboprophylaxis), and scores of 5 or more indicate high VTE risk (6.0% risk in the absence of thromboprophylaxis).

Some subgroups of patients are at considerably higher risk for perioperative VTE, namely those with very recent VTE (i.e., within prior 3 months) and those with a history of VTE associated with a high-risk inherited thrombophilia.[350] For individuals with a very recent VTE episode, elective surgery should be delayed until 3 or more months have elapsed since the episode (during which time they should be anticoagulated).[351] Specifically, the risk of recurrent VTE is highest during the first 3 to 4 weeks after the initial episode; this risk then decreases over the next 2 months. Hereditary high-risk thrombophilias include Factor V Leiden, antithrombin III deficiency, protein C deficiency, protein S deficiency, prothrombin gene mutation, and antiphospholipid antibodies. Factor V Leiden and prothrombin gene mutations are the most common causes, together comprising up to 60% of cases.[352]

BOX 31.12 Modified Caprini Risk Assessment Model for Venous Thromboembolism

1 Point Each

- Age 41–60 years
- Minor surgery
- BMI > 25 kg/m2
- Swollen legs
- Varicose veins
- Pregnancy or postpartum
- History of unexplained or recurrent spontaneous abortion
- Oral contraceptives or hormone replacement
- Sepsis (<1 month)
- Serious lung disease, including pneumonia (<1 month)
- Abnormal pulmonary function
- Acute myocardial infarction
- Heart failure (<1 month)
- History of inflammatory bowel disease
- Medical patient at bed rest

2 Points Each

- Age 61–74 years
- Arthroscopic surgery
- Major open surgery (>45 min)
- Laparoscopic surgery (>45 min)
- Malignancy
- Confined to bed (>72 h)
- Immobilizing plaster cast
- Central venous access

3 Points Each

- Age ≥ 75 years
- History of VTE
- Family history of VTE
- Factor V Leiden mutation
- Prothrombin 20210A mutation
- Lupus anticoagulant
- Anticardiolipin antibodies
- Elevated serum homocysteine
- Heparin-induced thrombocytopenia
- Other congenital or acquired thrombophilia

5 Points Each

- Stroke (<1 month)
- Elective arthroplasty
- Hip, pelvis, or leg fracture
- Acute spinal cord injury (<1 month)

BMI, Body mass index; *VTE,* venous thromboembolism.

From Gould MK, Garcia DA, Wren SM, et al. Prevention of VTE in nonorthopedic surgical patients: antithrombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physicians evidence-based clinical practical guidelines. *Chest.* 2012; 141: e227S–e277S.

Patients having minor procedures such as dental, endoscopic, cataract, or superficial operations usually do not require interruption of anticoagulant therapy. In other individuals, withholding warfarin for 5 days typically allows the INR to decrease to normal if the baseline INR is in the usual therapeutic target (2.0 and 3.0). A longer interval may be needed if the baseline INR is higher (see section on “Preoperative Anticoagulant Therapy”). During the time without warfarin, patients may be at risk for recurrent thromboembolism; however, the risk is relatively small in all but the highest-risk patients (i.e., VTE in prior 3 months, or VTE with high-risk inherited thrombophilia). The decision to bridge with intravenous unfractionated heparin or with LMWH subcutaneously in high-risk patients must be made collaboratively with the treating physician.

Preoperative Anticoagulant Therapy. Outpatient oral anticoagulant therapy includes vitamin K antagonists (e.g., warfarin) and DOACs. These agents increase perioperative bleeding, except in the case of very minor procedures. Thus, they should only be continued perioperatively if an individual does not have patient-related risk factors for bleeding (e.g., liver disease, abnormal renal function, prior bleeding complications), is scheduled for procedures without important bleeding risk (e.g., dental extraction, simple cutaneous procedures, cataract surgery without bulbar blocks), and is not being considered for neuraxial anesthesia. Otherwise, anticoagulant therapy must be temporarily discontinued before surgery.

Typically, vitamin K antagonists should be stopped 5 days before surgery, with consideration for a longer discontinuation period if the initial INR value is more than 3.0. Ideally, the INR should be rechecked within 24 hours before surgery,[195] and a low dose of oral vitamin K (1 to 5 mg administrated orally or subcutaneously) administered for any INR result greater than 1.5. Vitamin K has an effect within 6 to 10 hours after oral or subcutaneous administration (more predictable with oral administration), and it peaks within 24 hours to 48 hours.[353] Administration of higher doses may lead to warfarin resistance when therapy is initiated again. Some patients undergoing elective lower extremity joint replacement surgery may also receive an initial dose of warfarin before surgery for perioperative thromboprophylaxis. The 2018 American Society of Regional Anesthesiologists (ASRA) guidelines state that neuraxial anesthesia can still be performed in these patients when only a single dose of warfarin has been administered within a period of 24 hours or less before surgery.[196]

Patients are increasingly receiving DOACs for long-term anticoagulation, typically for nonvalvular atrial fibrillation, although some individuals may be prescribed low-dose DOAC therapy for IHD.[91] The timing of preoperative discontinuation of DOACs should be guided by the specific drug prescribed, expected procedural bleeding risk, renal function (based on estimated GFR), and planned use of neuraxial anesthesia. Some proposed approaches for preoperative DOAC discontinuation are outlined in Tables 31.11 and 31.12.[195-197]

Patients may require temporary bridging therapy during the intervening period between discontinuation of vitamin K antagonist therapy and the date of surgery. Such bridging therapy is generally not needed after interruption of DOACs because of their relatively short half-lives. *Most* patients with nonvalvular atrial fibrillation do not require bridging therapy if their anticoagulant therapy is temporarily discontinued before surgery (see section on "Atrial Fibrillation").[195,198] Conversely, many patients with mechanical heart valves will require bridging therapy, with the decision based on the location of the mechanical heart valve and nature of planned surgery (see Box 31.4).[173] Additionally, some patients who are at very high risk for recurrent VTE (e.g., VTE episode within prior 3 months) may also require bridging therapy. In general, decisions to use bridging therapy with intravenous unfractionated heparin or LMWH must be individualized, account for patients' risks of bleeding while on bridge therapy, and be made collaboratively with the treating physician.

If bridging is planned, either LMWH or intravenous unfractionated heparin can be started 2 or more days after the last administrated dose of vitamin K antagonist (e.g., warfarin). Bridging therapy should be started once the INR drops to under 2.0.[195] There are several available options for LMWH (e.g., enoxaparin, dalteparin). The specific choice and dose should be selected based on consultation with a hematologist or the patient's treating physician. For patients with impaired renal function (eGFR < 30 mL/min), intravenous heparin bridging is preferable, although some LMWH dosing adjustments remain possible if eGFR is in the range between 15 and 30 mL/min.[195] Intravenous unfractionated heparin is usually discontinued approximately 6 hours before the surgery to allow for normal intraoperative coagulation. The last dose of *bridging dose* LMWH should be given 24 hours preoperatively to allow normalization of coagulation by the time of surgery (based on an assumption of normal renal function). Both unfractionated heparin and LMWH are contraindicated in patients with an allergy to heparin or a history of HIT. Options for bridging therapy in such patients include argatroban (intravenous infusion), bivalirudin (intravenous infusion), fondaparinux (subcutaneous), or oral DOACs. The specific management strategy should be selected following consultation with a hematologist.

Based on the 2018 ASRA guidelines,[196] recommendations for management of preoperative anticoagulant therapy are more conservative if perioperative neuraxial techniques are being considered. These guidelines recommend that warfarin should be discontinued 5 or more days before surgery, and a repeat preoperative INR should confirm a normalized value before neuraxial blocks are performed.[196] The recommended intervals for timing of neuraxial blocks after discontinuing DOAC therapy are outlined in Table 31.11. The last *prophylactic* dose of LMWH should be 12 or more hours before any planned neuraxial block, whereas the last *therapeutic* dose (including bridging therapy) of LMWH should be 24 or more hours beforehand. Preoperative unfractionated intravenous heparin should be stopped 6 or more hours before planned spinal or epidural anesthesia.[196] In addition, return to normal coagulation can be monitored using aPTT or anti-factor Xa activity. Though the safety of performing neuraxial techniques in the presence of low-dose subcutaneous unfractionated heparin (i.e., 5000 units twice daily) has been described,[354] the 2018 ASRA guidelines include a Grade 2C recommendation for waiting 4 to 6 hours after subcutaneous injection before performing neuraxial blocks in patients receiving subcutaneous unfractionated heparin (i.e., 5000 units 2 or 3 times daily).[196] This Grade 2C rating indicates that the recommendation was relatively weaker ("*conflicting evidence or opinion on the usefulness*") and based entirely on case reports or expert opinion.[196] Any patients receiving fibrinolytic and thrombolytic drugs should not receive neuraxial anesthesia.

Preoperative Antiplatelet Therapy. Traditionally, aspirin has been discontinued before surgery (often 7-10 days before surgery) because of concern about increased bleeding. A withdrawal period of 7 to 10 days is likely excessive, especially because new platelets formed after aspirin discontinuation (half-life ≈15 minutes) are not inhibited. Since 10% of platelets are turned over every 24 hours, and about 50,000/mm^3 of normal functioning platelets are needed to control surgical bleeding, it is likely that aspirin need only be stopped 3 days before surgery to mitigate risks of increased bleeding. Continuation of aspirin until the time of surgery leads to increased bleeding during major noncardiac surgery,[136] but not during cardiac surgery.[355] *Withdrawing* aspirin itself has important theoretical risks with respect to a rebound hypercoagulable state and increased cardiac risk,[141,356] however, these theoretical risks have not been supported by data from large randomized trials.[136,355] Therefore, a reasonable standard approach for most surgical patients is to discontinue aspirin temporarily 3 days before surgery, with some notable exceptions. Specifically, aspirin should be continued in any patient with a prior PCI,[144] high-grade IHD, or high-risk CVD (e.g., stroke within prior 9 months).[212] Continuation of aspirin is not a contraindication to performance of neuraxial blocks.[196]

P2Y$_{12}$ inhibitors are the other relatively common type of antiplatelet medications that might be encountered during preoperative evaluation, especially among patients with known IHD or CVD. These medications include oral medications (clopidogrel, ticagrelor, prasugrel, ticlopidine) and an intravenous formulation (cangrelor). Aside from the case of patients with a recent PCI (see section on "Coronary Stents"), P2Y$_{12}$ inhibitor therapy should be temporarily discontinued before elective surgery. The usual recommended time interval for discontinuing these medications before surgery (including cases where neuraxial blocks are planned) is 5 to 7 days for clopidogrel, 5 to 7 days for ticagrelor, 7 to 10 days for prasugrel, 10 days for ticlopidine, and 3 hours for cangrelor.[196]

Some patients with either PAD or CVD may be on long-term therapy with dipyridamole, which causes vasodilation and impairment of platelet function. The drug is available as an immediate-release formulation, as well as an extended-release formulation combined with aspirin (i.e., Aggrenox). There are minimal data on the safety of continuing dipyridamole in patients undergoing surgery; current ASRA guidelines recommend discontinuing extended-release dipyridamole 24 hours before performing any neuraxial block.[196] Information on the perioperative safety of other antiplatelet therapies (e.g., glycoprotein IIb/IIIa inhibitors) is also limited. Platelet glycoprotein IIb/IIIa inhibitors (e.g., abciximab, eptifibatide, tirofiban) exert profound effects on platelet aggregation. Following administration, the time to restoration of normal platelet aggregation is 24 to 48 hours for abciximab, and 4 to 8 hours for eptifibatide and tirofiban. Neuraxial techniques should be avoided until platelet function has recovered after platelet glycoprotein IIb/IIIa inhibitor administration.[196]

NEUROLOGIC DISEASE

The preoperative history in a patient with neurologic disease should focus on recent exacerbations, prior investigations, and therapy (both current and prior). The basic neurologic examination should evaluate mental status, speech, cranial nerves, gait, motor function, and sensory function. This baseline determination also allows for comparison of any new postoperative deficits.

Cerebrovascular Disease

The major clinical manifestation of CVD is acute stroke with more than 10 million new strokes per year worldwide. In addition, about 6.5 million individuals die annually from stroke, making it the second leading cause of death globally.[357] The two main categories of stroke are hemorrhagic stroke and ischemic stroke. Hemorrhagic stroke is largely related to either intracerebral hemorrhage or subarachnoid hemorrhage. Common causes of intracerebral hemorrhage include hypertension, trauma, coagulopathies, illicit drug use (i.e., amphetamines, cocaine), and arteriovenous malformations (AVMs). Causes of subarachnoid hemorrhage are bleeding from aneurysms and AVMs (see section on "Aneurysms and Arteriovenous Malformations"). Ischemic stroke may be related to thrombosis of an artery through several different mechanisms (e.g., atherosclerosis, arterial dissection), embolism (e.g., related to atrial fibrillation), or systemic hypoperfusion (e.g., cardiac arrest). The other major manifestation of CVD is a TIA, which is a transient episode of neurologic dysfunction caused by focal ischemia in the brain, spinal cord, or retina, but without infarction.[358]

CVD has important perioperative implications. It is a risk factor for postoperative complications, including cardiac events,[97] stroke,[132,359,360] and death.[77] Furthermore, the risks of postoperative cardiac complications and recurrent stroke are particularly increased when elective noncardiac surgery is performed within 9 months after a prior stroke[212] or when surgical aortic valve replacement is performed within 3 months after a prior stroke.[212] Importantly, if emergency surgery needs to be performed after a stroke, it may be preferable to *not* delay surgery. Specifically, while the risks of postoperative cardiovascular complications are very high when emergency surgery is performed within 2 weeks after an ischemic stroke, these risks were reduced when surgery proceeded within 72 hours after the stroke.[361] This temporal pattern may be explained by progressively worsening cerebral autoregulation during the first 5 days after an ischemic stroke (which then recovers over the next 3 months).[362]

The preoperative evaluation should focus on the timing, presentation, etiology, and treatment of prior strokes or TIAs. It is important to document the etiology in order to distinguish carotid stenosis (i.e., atherosclerosis) from cardioembolic disease. Causes of cardiac emboli include stasis (i.e., atrial fibrillation, severe cardiomyopathy, ventricular aneurysm), thrombogenic (i.e., valvular heart disease, prosthetic heart valve), and paradoxical venous source (e.g., patent foramen ovale). The physical examination should include a brief neurologic exam to identify any preexisting deficits, auscultation for carotid bruits, and a precordial assessment to assess for murmurs or extra heart sounds. Depending on the underlying basis for CVD (i.e., atherosclerosis, atrial fibrillation), patients may be on long-term therapy with aspirin, $P2Y_{12}$ inhibitors (e.g., clopidogrel), vitamin K antagonists, and DOACs. Both vitamin K antagonists and DOACs should be temporarily discontinued before surgery (see section on "Atrial Fibrillation"). Similarly, $P2Y_{12}$ inhibitor therapy should be interrupted before surgery, with the possible exception of cases with very recent coronary stent implantation (see section on "Coronary Stents"). Continuing aspirin perioperatively does not prevent cardiovascular complications,[136] but leads to an increased risk of major bleeding (a risk factor for perioperative stroke).[132] Nonetheless, selective continuation of aspirin can be considered in patients with high-risk atherosclerotic CVD or recent stroke (i.e., previous 9 months).[212] In other cases, aspirin should be temporarily held 72 hours before surgery.[136] In addition, concomitant CVD should be carefully considered in any decision to initiate new β-adrenergic blocker therapy in a patient awaiting noncardiac surgery. Although β-blockade does decrease perioperative cardiac risk, it also significantly increases the risk for acute postoperative stroke.[132,133]

Asymptomatic Carotid Bruit

The presence of a carotid bruit significantly increases the likelihood of a significant lesion (i.e., 70%-99% stenosis) in both symptomatic or asymptomatic patients.[26] Thus, a newly discovered carotid bruit should prompt a careful search for any evidence of prior strokes or TIA, especially if the planned surgical procedure involves neck manipulation. At-risk individuals include those with risk factors for CVD (e.g., hypertension, smoker, diabetes mellitus, hyperlipidemia, IHD, PAD), as well as patients with prior head and neck radiation exposure. Patients may not volunteer pertinent symptoms until they are specifically probed, especially if the symptoms were transient. The anesthesiologist should specifically inquire about *amaurosis fugax*, dysphagia, dysarthria, and other symptoms of cerebrovascular insufficiency. Carotid Doppler ultrasound studies are simple, effective tools to evaluate suspicious carotid bruits. Significant abnormalities on Doppler studies may entail a referral to a neurologist or vascular surgeon. The risk of stroke in patients who have truly asymptomatic bruits is 1% to 2% per year, with most strokes preceded by transient symptoms.[363] No evidence indicates that truly asymptomatic bruits increase the risk of *perioperative* stroke.[364]

Seizure Disorder

The seizure type (e.g., *grand mal*, absence) and specific symptoms (e.g., staring, focal findings) are important to document in the preoperative evaluation. For example, absence (previously *petit mal*) seizures may be particularly difficult to recognize after surgery because they lack generalized motor signs. Hence, typical symptoms, such as staring and obtundation, may be misinterpreted as residual anesthetic effects in the postoperative period. It is important to determine the etiology of the seizure disorder because of possible associated morbidities, which include brain tumors, aneurysms, AVMs, classic epilepsy, drug toxicity, electrolyte disorders, infections, CVD, sickle cell disease, and SLE.

The anesthesiologist should document the anticonvulsant dosing regimen and adequacy of seizure control. Routine measurement of serum drug levels of anticonvulsants is not indicated unless there are concerns about drug toxicity or ongoing breakthrough seizures. Indeed, patients with good control of seizures may have levels outside the therapeutic range. Drug levels are highly influenced by when the blood draw occurs relative to the timing of drug administration. In general, trough levels should be measured. Anti-seizure medications have multiple side effects (e.g., bone marrow suppression, macrocytic anemia, leucopenia, hyponatremia), and testing may be needed based on suspected abnormalities. The most commonly ordered tests are CBC and electrolyte concentrations. All anticonvulsant therapy should be continued perioperatively. A patient with poorly controlled or new-onset seizures should be evaluated by a neurologist before any non-emergent surgery.

Multiple Sclerosis

Multiple sclerosis is believed to be an inflammatory immune disorder with two general clinical patterns: exacerbating-remitting and chronic progressive. Symptoms can include ataxia, motor weakness, sensory deficits, autonomic dysfunction, emotional lability, bladder or bowel dysfunction, and visual disturbances. Exacerbations of multiple sclerosis can be triggered by stress, infections, pregnancy, and elevated temperatures. Various treatments have been tried, including corticosteroids, immunosuppressants, monoclonal antibodies, plasmapheresis, benzodiazepines, and baclofen. The preoperative evaluation should document the history and pattern of disease, especially symptoms and physical deficits affecting the respiratory system (including oxygen saturation). Medications, previous triggers, and preexisting neurologic deficits should be documented. Testing is generally directed toward associated disturbances (e.g., chest radiography and CBC if pulmonary infection is suspected) and any medication side effects. For example, azathioprine can suppress bone marrow or affect liver function, cyclophosphamide may cause electrolyte abnormalities, and corticosteroids can cause hyperglycemia. Patients with stable minor disease require no special testing. Related medications should be continued on the day of surgery. No clear association has been shown between the type of anesthetic or a specific anesthetic drug and disease exacerbations. Nonetheless, regional anesthesia may offer theoretical advantages for patients with respiratory compromise or cognitive dysfunction.

Aneurysms and Arteriovenous Malformations

Aneurysms and AVMs can occur in the cerebral and spinal vascular beds. These lesions may be intact, ruptured, symptomatic, or incidental asymptomatic findings. Associated risk factors include polycystic kidney disease, fibromuscular dysplasia, type IV Ehlers-Danlos syndrome, and a family history. Some AVMs become large enough to exert a mass effect. The risk of aneurysmal bleeding, and possibly AVM bleeding, increases during pregnancy. Most patients have minimal symptoms before a rupture. A rupture can result in altered mental status, syncope, increased intracranial pressure, inappropriate antidiuretic hormone (ADH) secretion, and hemodynamic changes (i.e., bradycardia, tachycardia, ectopic beats). Typical testing includes an ECG and blood sampling to measure electrolyte, glucose, and creatinine concentrations. Chest radiography, echocardiography, and neurologic imaging (e.g., computed tomography scan) are also often needed. Importantly, the ECG changes seen following a rupture, which often include ST-segment and T-wave changes, mimic those seen with myocardial ischemia. In addition, troponin concentrations are often elevated, while echocardiography may reveal significant cardiac dysfunction with depressed contractility and wall motion abnormalities. Although the bleeding may be primarily responsible for these cardiovascular changes, concomitant IHD or preexisting cardiomyopathy should also be considered. Measures aimed at controlling increased intracranial pressure, arterial blood pressure, and blood glucose are important.

Parkinson Disease

Parkinson disease is a degenerative disorder of the basal ganglia characterized by failure of dopamine secretion and diminished inhibition of the extrapyramidal motor system. Patients typically have diminution of spontaneous movements, rigidity (cogwheel rigidity is classic), resting tremor, masked facies, difficulty speaking, difficulty walking, depression, and dementia. Autonomic dysfunction (including orthostatic hypotension), excessive salivation, and impaired thermoregulation may also occur. Patients are at risk of pulmonary complications resulting from difficulty swallowing, altered mental status, increased aspiration risk, and ventilatory muscle dysfunction. Pharmacologic treatments include levodopa, dopamine agonists (e.g., bromocriptine, pramipexole, ropinirole, rotigotine), monoamine oxidase type B inhibitors (e.g., selegiline, rasagiline, safinamide), anticholinergic agents (e.g., trihexyphenidyl, benztropine), amantadine, and catechol-O-methyl transferase inhibitors (tolcapone, entacapone). Levodopa can cause dyskinesias (i.e., dystonic and myoclonic involuntary movements). Some individuals also undergo implantation of deep brain stimulators to manage their symptoms.

Preoperative evaluation should assess the pulmonary system, signs of dysphagia, and degree of disability. Evidence of significant pulmonary symptoms or possible infection requires chest radiography, pulmonary consultation, and possible delay of the procedure for improvement. All associated medications should be continued. Abrupt withdrawal of levodopa may exacerbate symptoms (especially dysphagia and chest wall rigidity) or precipitate neuroleptic malignant syndrome. The latter disorder is characterized by autonomic instability, altered mental status, rigidity, and fever. Some medications encountered in the perioperative setting, such as metoclopramide and phenothiazines, may exacerbate symptoms of Parkinson disease by interfering with dopamine. Individuals with deep brain stimulators require deactivation of the devices before any procedures in which electrocautery will be used. The specific device should be identified, along with the severity of disease symptoms when the device is turned off. Perioperative management of the device ideally should be coordinated with the surgeon and the clinician managing the device.

Neuromuscular Junction Disorders

Myasthenia gravis is an autoimmune disorder of skeletal muscle neuromuscular junctions that is caused by antibodies against nicotinic acetylcholine receptors. The disease is characterized by skeletal muscle weakness that worsens with activity and improves with rest. Cardiac and smooth muscle function is unaffected. Weakness is exacerbated by stress, infections, hypokalemia, medications (e.g., aminoglycosides, propranolol, ciprofloxacin, clindamycin), and surgery. A classification system for severity of myasthenia gravis is presented in Box 31.13. Patients with myasthenia gravis commonly have other autoimmune diseases, such as rheumatoid arthritis, polymyositis, and thyroid disorders.

Ocular symptoms (i.e., diplopia, ptosis) are almost always present; often, they are the presenting complaint or sole complaint. Cranial nerve and bulbar involvement are common, with an associated aspiration risk related to pharyngeal and laryngeal muscle weakness. Affected individuals may have thymic hyperplasia and tumors. Since the thymus is located in the anterior mediastinum, thymic enlargement has potential implications for anesthesia care (see section on "Mediastinal Masses"). Patients are usually treated with thymectomy, acetylcholinesterase inhibitors (e.g., pyridostigmine, neostigmine), immunosuppressants (corticosteroids, azathioprine, mycophenolate, cyclosporine), plasmapheresis, and intravenous immunoglobulins. Worsening symptoms may reflect worsening disease (i.e., myasthenic crisis) or excessive acetylcholinesterase inhibitor treatment (i.e., cholinergic crisis). A short-acting anticholinesterase (edrophonium) can help distinguish the two states, since only a myasthenic crisis improves with more anticholinesterase. Plasmapheresis and intravenous immunoglobulins have been used to treat myasthenic crises and prepare patients for surgery, but still require several days to weeks to produce improvement.

All medications (with associated doses) should be documented and continued perioperatively. These drugs may also have implications themselves. For example, patients taking azathioprine require a CBC and liver function tests because of drug-induced bone marrow suppression and liver dysfunction. Patients treated with corticosteroids need measurement of blood glucose concentration, as well as possible perioperative corticosteroid supplementation. Since ventilatory function can be compromised, preoperative PFTs may also be indicated for selected patients, particularly those suspected of having severely affected ventilatory function. PFTs may be particularly helpful if patients are being considered for ambulatory surgery, especially in freestanding surgical centers. Drugs that can exacerbate myasthenic symptoms should also be avoided.

Lambert-Eaton syndrome is similar to myasthenia gravis, with muscle weakness including oculobulbar involvement and dysautonomia. It is caused by antibodies against voltage-gated calcium channels that result in decreased acetylcholine release. It is not associated with thymic abnormalities, but commonly occurs with malignant diseases, especially small cell lung cancer and gastrointestinal tumors. The other distinguishing feature of this disorder is that the muscle weakness classically improves with activity and is worse after inactivity. In addition to acetylcholinesterase inhibitors, typical treatments include 3,4-diaminopyridine, which is a selective potassium channel blocker. Preoperative evaluation and management are similar to those for myasthenia gravis. All related medications should be continued perioperatively.

BOX 31.13 Osserman Classification System for Myasthenia Gravis Clinical Classification System

Class I: Ocular myasthenia
Class IIA: Mild generalized myasthenia with slow progression: no crises, responsive to drugs
Class IIB: Moderately severe generalized myasthenia: severe skeletal and bulbar involvement but no crises; drug response less than satisfactory
Class III: Acute fulminating myasthenia: rapid progression of severe symptoms, with respiratory crises and poor drug response
Class IV: Late severe myasthenia, same as III but progression over 2 years from class I to II

Data from Osserman KE, Genkins G. Studies in myasthenia gravis: review of a twenty-year experience in over 1200 patients. *Mt Sinai J Med*. 1971;38:497–537.

Muscular Dystrophies and Myopathies

Muscular dystrophies and myopathies are inherited disorders that affect the neuromuscular junction. They share many similarities but do have a few differences. The hallmark of these disorders is progressive skeletal muscle weakness that commonly leads to respiratory failure. No effective therapy is available. Many individuals have associated cardiomyopathies and possible association with malignant hyperthermia.

Duchenne and Becker muscular dystrophies are X-linked recessive disorders that occur primarily in males. Affected individuals have elevated creatine phosphokinase levels, often preceding the onset of symptoms. Male patients with a family history of either Duchenne or Becker muscular dystrophy should be considered at risk (even when they have not been formally tested), and they require precautions similar to those in patients with diagnosed disease. Cardiomyopathy and respiratory failure are the usual causes of death. Female carriers of the abnormal gene may have dilated cardiomyopathy despite having no other manifestations of the disease. The preoperative evaluation should focus on the cardiovascular (e.g., palpitations, dyspnea, chest pain, syncope, orthopnea, dependent edema) and pulmonary (e.g., aspiration, pneumonia) systems. Potentially helpful additional preoperative tests include ECGs, PFTs, and echocardiography. Facioscapulohumeral muscular dystrophy (also known as faciohumeroscapular or Landouzy-Dejerine muscular dystrophy) is an autosomal dominant disorder that affects both sexes and causes a slow, progressive weakness of muscles in the shoulders and face. Cardiomyopathy occurs much less frequently than in other dystrophies, but arrhythmias have been reported. Limb-girdle dystrophies have a variable genetic inheritance pattern and primarily affect the muscles of the shoulders and pelvis. Conduction abnormalities are present in some patients, although frank cardiomyopathies are less frequent. The preoperative evaluation is largely similar to that described previously for Duchenne muscular dystrophy.

Myotonic Dystrophies. Myotonia is characterized by prolonged contraction and delayed relaxation of muscles. It is a common symptom of several dystrophies, including classic myotonic dystrophy, congenital myotonic dystrophy, myotonia congenital, and central core disease. Myotonic dystrophy, which is the most common of these conditions, is an autosomal dominant inherited disorder affecting both sexes. Congenital myotonic dystrophy is a severe form of this disease that manifests in infancy, often in the children of affected mothers. The classic findings are severe muscle wasting, typically involving the diaphragm, face, hands, pharynx, and larynx. Cold temperatures can often trigger myotonia. The disease severity is variable, with symptoms often not apparent until the second or third decade of life; hence, a family history is important. Cardiomyopathies, arrhythmias, and conduction abnormalities are common, while some patients also have cardiac valvular abnormalities. Cardiac involvement may not correlate with the degree of atrophy or weakness in skeletal muscle. Once an affected individual shows any evidence of second- or third-degree AV block, a pacemaker should be implanted (even if the patient is asymptomatic) because an unpredictably rapid progression of conduction disease may occur. Given this potential for rapid disease progression, pacemaker placement may be considered in patients with first-degree AV block, regardless of symptoms. Affected individuals are also at risk for aspiration, pneumonia, respiratory failure, and postoperative pulmonary complications. Central core disease is a rare disorder caused by deficiency of mitochondrial enzymes. The name derives from findings of muscle biopsies, which reveal “cores” of abnormalities. Affected individuals have proximal muscle weakness, scoliosis, and sometimes cardiomyopathies. As with myotonic dystrophy, patients are at risk for respiratory failure and aspiration. Myotonia congenita is a hereditary disorder that involves only skeletal muscles, causes less severe symptoms, and does not cause cardiac abnormalities.

Myotonia was historically thought to predispose patients to malignant hyperthermia, however, current evidence indicates that they are *not* at increased risk.[365] Nonetheless, succinylcholine should still be avoided in these patients because it may cause diffuse muscle contraction. Symptomatic treatments for myotonic contractions include corticosteroids, quinine, and procainamide; otherwise, these diseases have no cure. These treatments should be continued perioperatively. The preoperative evaluation focuses on the cardiopulmonary system, with special emphasis on evaluating for pulmonary infection, heart failure, syncope, conduction abnormalities, and valvular abnormalities. Preoperative testing includes an ECG, echocardiogram (except for myotonia congenita), and chest radiograph (if symptoms of pulmonary disease are present). Evidence of a conduction abnormality on ECG should trigger a cardiology consultation. Myotonia is not inhibited by regional anesthesia, but local anesthetic infiltration into muscle may provide symptomatic relief.

Central Nervous System Tumors

Pituitary tumors are classified as functioning (associated with endocrine abnormalities) versus nonfunctioning, as well as benign (adenomas are the most common pituitary lesion) versus malignant. The tumor can have mass effects that lead to associated symptoms, such as headaches, visual field defects, and increased intracranial pressure (with resulting gait disturbances, vomiting, cranial nerve deficits, bladder incontinence, bowel incontinence). Other symptoms may be related to pituitary insufficiency (e.g., hypoadrenalism, hypothyroidism, infertility) or overactivity. Manifestations of pituitary overactivity include Cushing syndrome from ACTH-secreting tumors; acromegaly from growth hormone secretion; hyperthyroidism from TSH production; and gynecomastia, lactation, and sex hormone-related changes from prolactin and gonadotropin (follicle stimulating and luteinizing hormones) secretion. These hormones are all produced by the anterior lobe of the pituitary and are controlled by a feedback loop from the hypothalamus. The posterior pituitary stores and secretes vasopressin and oxytocin, which are synthesized in the hypothalamus.

Acromegaly results in enlargement of connective tissue, bone, and visceral organs. Affected individuals have an enlarged jaw (i.e., macrognathia), nose, feet, hands, pharyngeal tissue, and laryngeal tissue (including macroglossia and enlarged epiglottis). Affected individuals have increased risks of sleep apnea (both central and obstructive), neuropathies (from nerve entrapment), hypertension, diastolic dysfunction, and cardiac valvular abnormalities. IHD, heart failure, diabetes mellitus, hypothyroidism, and difficult airway management (i.e., mask ventilation, laryngoscopy, intubation) may also occur. The preoperative evaluation should document any chest pain, dyspnea, snoring, numbness, polydipsia, headaches, and visual disturbances. The physical examination focuses on blood pressure, airway examination, murmurs, neurologic findings, and peripheral edema. It is important to plan for possible difficult airway management and inform the patient about the possible use of awake fiberoptic intubation. Preoperative testing may include an ECG and blood sampling for electrolyte concentration, glucose concentration, and thyroid function tests. TSH increases production of thyroid hormones (T_3 and T_4) by the thyroid gland (see section on “Thyroid Disease”). Prolactin- and gonadotropin-secreting tumors have little impact on anesthetic management, but their symptoms may alert clinicians to an undiagnosed pituitary tumor.

Posterior pituitary tumors result in failure to secrete vasopressin or ADH, which regulates renal water excretion. A deficiency results in diabetes insipidus, which is characterized by excessive urine output from a failure to reabsorb water. Unless treated with DDAVP, these patients may develop hypernatremia and volume depletion. The anesthesiologist should therefore carefully evaluate patients’ intravascular volume status and conduct blood sampling for electrolyte concentrations and creatinine concentrations. Patients with pituitary tumors, pituitary apoplexy (hemorrhage into pituitary, which is associated with hypertension, trauma, or pregnancy), or previous pituitary tumor resection may require hormone replacement therapy (i.e., corticosteroids, thyroid replacement, DDAVP). These medications must not be interrupted during the perioperative period. The adequacy of replacement therapy can be determined based on the clinical evaluation, as well as blood sampling for electrolyte concentrations, creatinine concentrations, and thyroid function tests.

Other intracranial tumors include gliomas (45% of tumors), astrocytomas, ependymomas, medulloblastomas, oligodendrocytomas (malignant and highly lethal), benign meningiomas (15% of tumors), schwannomas, craniopharyngiomas, and dermoid tumors. Metastatic lesions (6% of intracranial tumors) can also occur with virtually all types of primary malignant diseases. Common sources of metastatic intracranial lesions include breast, colorectal, and lung cancers. Most intracranial tumors are detected either incidentally, or when patients develop seizures or symptoms related to mass effect. Symptoms of mass effect include headaches, strokelike symptoms, vomiting, visual disturbances, altered cognitive function, and ataxia. If the intracranial pressure becomes elevated, hypertension, bradycardia, arrhythmias, ECG abnormalities, and brainstem herniation may occur. Careful assessment of neurologic deficits is important. For patients with metastatic lesions, issues pertaining to the primary malignant disease and previous treatment (e.g., chemotherapy, radiation, corticosteroids, anticonvulsants) must be clarified. Continuation of preexisting corticosteroids (to treat cerebral edema) and anticonvulsant medications is important.

MUSCULOSKELETAL AND CONNECTIVE TISSUE DISEASES

These disorders are characterized by musculoskeletal deformities and chronic inflammation. Assessment of deformities is important because of their potential implications for airway management and regional anesthesia technique. Chronic inflammation—which occurs with rheumatoid arthritis, SLE, and systemic sclerosis—can cause vasculopathy and multiorgan dysfunction. Affected organ systems may include cardiovascular, pulmonary, renal, hematologic, integumentary, gastrointestinal, central nervous, and peripheral nervous systems.

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic autoimmune disorder that primarily affects joints, but it often also affects multiple organ systems. The disease affects approximately 1% of the population, and women are 2 to 3 times more likely to be affected as are men.[366] Distal joints are involved more often than proximal, often in a symmetric pattern. Joint involvement is characterized by inflammation that can progress to severe deformity, although the disease course can vary dramatically. The temporomandibular joints and cricoarytenoid cartilage can be involved, resulting in limited mouth opening, hoarseness, and possible difficulties with airway management. Atlantodens subluxation and instability of the cervical spine can also occur. Subluxation, which is caused by ligamentous laxity, as opposed to joint disease, may also occur, although the prevalence appears to be decreasing with the advent of improved disease modifying agents. Cervical spine disease can be asymptomatic. IHD, pericardial effusions, aortic regurgitation, and conduction abnormalities may be present in affected individuals. Symptoms of myocardial ischemia may be masked in patients with rheumatoid arthritis because of impairment of functional status by concomitant joint disease. In addition, exertional dyspnea because of heart failure may be confused with pulmonary involvement. Pulmonary manifestations include restrictive lung disease secondary to decreased thoracic mobility, pulmonary fibrosis, and pleural effusions. Patients have an increased risk of renal dysfunction secondary to both vasculitis and long-term NSAID use. Peripheral neuropathy can result from vasculitis or entrapment. Anemia, leukocytosis, thrombocytosis (from chronic inflammation), and thrombocytopenia (from splenomegaly) may be present. Patients may also have rheumatoid nodules that occur subcutaneously (usually over extensor joints) or in the lungs.

The preoperative examination must document symptoms related to the many organ systems affected by rheumatoid arthritis. Special detail is directed to the neurologic, airway, pulmonary, and cardiovascular systems. Documentation of deformities and neurologic deficits is important to establish a baseline level of function. Significant hoarseness should prompt an evaluation by an otolaryngologist to assess the mobility of the vocal cords and the presence of cricoarytenoid arthritis. A careful history may elicit neurologic deficits, neck pain, upper extremity pain, or crunching sound with neck movement. Indications for preoperative cervical spine radiographs include neurologic findings, long-standing severely deforming disease, or procedures requiring prone positioning or manipulation of the cervical spine. The specific radiographs required are anteroposterior and lateral cervical spine films with flexion, extension, and open-mouth odontoid views.[367] Significant abnormalities (i.e., anterior atlas-dens interval >9 mm or posterior interval <14 mm) require consultation with a neurologist or neurosurgeon. Notably, disease duration, severity, and symptoms do not correlate with cervical spine subluxation. New or worsening pulmonary symptoms should prompt further evaluation with pulse oximetry, chest radiographs, PFTs, or possibly a pulmonary consultation. Muffled heart sounds, pericardial rubs, and low voltage on an ECG suggest a pericardial effusion, which necessitates an echocardiogram. Any suspicious murmur merits an echocardiogram in these patients. Because rheumatoid arthritis is associated with a very high prevalence of IHD, patients may require ECGs and possible cardiac stress testing (with subsequent cardiology referral as indicated). Other preoperative tests include blood sampling for CBC and creatinine concentrations.

Advanced planning for management of potential difficult airways is important, including discussion of regional anesthetic options and possible awake fiberoptic intubation. When possible, corticosteroids, analgesics, and nonbiological disease modifying agents (e.g., methotrexate, leflunomide, hydroxychloroquine, sulfasalazine) should be continued, although consideration can be given to stopping NSAIDs 2 to 3 days before surgery. There are more concerns regarding whether biological disease modifying agents (i.e., tumor necrosis factor alpha antagonists) should be stopped before surgery, especially since continued treatment may predispose patients to postoperative infections. Several guidelines recommend holding these agents before surgery,[368,369] although there is uncertainty regarding when treatment should be stopped relative to surgery. Especially since these drugs have different dosing cycles, patients with complex immunosuppressant therapy are best managed collaboratively with their rheumatologist, primary care physician, and surgeon. Stress-associated adrenal insufficiency may occur in patients taking preoperative corticosteroid therapy. Details on which patients warrant perioperative stress dose corticosteroids, as well as a suggested dosing regimen, are presented in the section on "Hypothalamic-Pituitary-Adrenal Disorders" and Table 31.15.

Ankylosing Spondylitis

Ankylosing spondylitis is a progressive inflammatory arthropathy that primarily affects the spine and sacroiliac joints, although peripheral joints may also be involved. It usually occurs in males. Ankylosing spondylitis can have important extraarticular manifestations, including uveitis, vasculitis, aortitis, and aortic insufficiency. Affected individuals may develop restrictive lung disease related to pulmonary fibrosis or chest wall movement restriction (joint fixation and kyphosis). Kyphosis can be so extreme that patients are unable to face forward, thereby making mask ventilation, direct laryngoscopy, and intubation very difficult. The patient's preoperative evaluation should focus on the cardiovascular, pulmonary, and musculoskeletal systems, with the physical examination including measurement of oxygen saturation on room air. The presence of a murmur on physical examination warrants an echocardiogram. If ventilatory compromise is suspected or present, a chest radiograph and PFTs are necessary. Most analgesic medications and non-biological disease modifying agents (e.g., sulfasalazine) can be continued preoperatively, although consideration can be given to stopping NSAIDs 2 to 3 days before surgery. Several guidelines recommend holding biological disease modifying agents (i.e., tumor necrosis factor alpha antagonists) before surgery,[368,369] although there is uncertainty regarding when treatment should be stopped relative to surgery. Especially since these drugs have different dosing cycles, patients with complex immunosuppressant therapy are best managed collaboratively with their rheumatologist, primary care physician, and surgeon. It is important to plan for perioperative airway management and inform the patient about the possibility of awake fiberoptic intubation. Peripheral nerve blocks are an option, but neuraxial anesthesia is often unsuccessful in the presence of severe spinal involvement.

Systemic Lupus Erythematosus

SLE is a systemic autoimmune disease that is predominantly caused by vasculitis. It has a variable course with flares and remission periods. SLE is more likely to affect females (i.e., seven-fold higher prevalence in adults), as well as individuals with East Asian or African-American ethnic backgrounds.[370] The multiorgan disease has musculoskeletal, cardiovascular, pulmonary, renal, neurological, dermatological, hematological, gastrointestinal, and constitutional manifestations. Common constitutional symptoms are fever and chronic fatigue. The fevers may be explained by disease activity itself, as well as frequent infections related to disease-induced immune dysfunction and immunosuppressant treatment. The musculoskeletal findings are typically a migratory arthritis of the small joints in the hands and feet. Many patients have dermatologic conditions including alopecia, photosensitivity, and a typical "butterfly rash" across the cheeks and nose. Vasospasm of the digits (i.e., Raynaud phenomenon), often associated with atrophy of nails and fingernails, can make it difficult to obtain pulse oximetry readings. Pulmonary manifestations include interstitial lung disease, pleural effusions, frequent respiratory infections, and pulmonary hypertension. Pulmonary hypertension, which can result from recurrent pulmonary emboli, pulmonary vasculopathy, and interstitial lung disease, carries a high risk of perioperative complications.[371] Cardiovascular involvement includes hypertension (often difficult to control), premature IHD, pericarditis, myocarditis, coronary artery vasculitis, cardiomyopathy, aseptic endocarditis, and pleural effusions. Neurologic disease includes cerebral vasculitis, stroke, CVD, cognitive dysfunction, seizures, peripheral neuropathy, headache, neuropsychiatric manifestations, and affective disorders. Lupus nephritis is a common end-organ complication that carries a poor prognosis and often results in ESRD. Patients with SLE may have anemia, leukopenia, thrombocytopenia, and antiphospholipid antibodies. Individuals with these antibodies typically have a prolonged aPTT, but are predisposed to pulmonary emboli, stroke, and recurrent venous or arterial thromboses.

The preoperative evaluation should assess all major organ systems and relevant medications. Patients with severe disease, infections, or exacerbations are best managed collaboratively with their rheumatologist or primary physician. The history should cover details on typical disease flairs (manifestations, timing, treatment), fevers, cardiovascular symptoms (e.g., dyspnea, chest pain, orthopnea), neurologic symptoms (e.g., stroke, seizures), renal disease, prior thromboembolic events, and fevers. Given the prevalence of IHD and CVD in these patients, the evaluation should include reviewing results of any previous relevant diagnostic studies (e.g., cardiac stress testing, echocardiography, computed tomography, MRI). The preoperative physical examination concentrates on the pulmonary (rales, decreased breath sounds), cardiac (pericardial rubs, murmurs, arrhythmias, jugular venous distention, peripheral edema), and nervous (motor deficits, sensory deficits, visual disturbances) systems. Helpful preoperative tests include an ECG and blood sampling for CBC, electrolyte concentrations, glucose concentrations, creatinine concentrations, and aPTT (unless the patient has a known antiphospholipid syndrome). Significant ECG abnormalities (e.g., conduction delays, arrhythmias, Q waves, low voltage) should prompt consideration for further testing, cardiology consultation, or pulmonology consultation. Other tests that may be considered include an INR (patients receiving warfarin), echocardiogram (murmurs, suspected heart failure, suspected effusion), chest radiograph (pulmonary symptoms or suspected heart failure), and PFTs (worsening or undiagnosed dyspnea). Patients with advanced cardiomyopathy, decompensated heart failure, pulmonary hypertension, systemic vasculitis, and recent or recurrent thromboembolism are considered to be at high risk, and they are best managed in concert with the appropriate specialists. Most medications, including corticosteroids and non-biological disease-modifying agents (e.g., hydroxychloroquine, cyclosporine, azathioprine, tacrolimus) should be continued. Patients on long-term corticosteroid therapy may need perioperative stress dose corticosteroids. Details on patient selection for such therapy, as well as a suggested dosing regimen, are presented in the section on "Hypothalamic-Pituitary-Adrenal Disorders" and Table 31.15. Medications that require temporary preoperative discontinuation include anticoagulant therapy; consultation with a hematologist may be necessary to plan perioperative anticoagulation management, including the possible need for bridging therapy. Similarly, patients with complex biological immunosuppressant therapy for SLE (e.g., belimumab) are best managed collaboratively with their rheumatologist.

Systemic Sclerosis

Systemic sclerosis (previously known as scleroderma) is an autoimmune multisystem disease that is characterized by excessive fibrosis. It occurs more commonly in females.[372] Aside from skin thickening, the most common skin manifestation is Raynaud phenomenon. Scleroderma has several variants, which are differentiated based on the extent of skin and internal organ involvement. *Localized scleroderma* involves just the skin, and no other organs. *Limited systemic sclerosis* has cutaneous manifestations "limited" to face and upper extremities, as well as systemic involvement in the gastrointestinal tract (e.g., dysphagia, reflux) and lungs (e.g., interstitial lung disease, pulmonary hypertension). *Diffuse systemic sclerosis* is characterized by generalized skin involvement and multiple end-organ damage. Manifestations include myocardial fibrosis, pericarditis, heart failure (right-sided and left-sided), coronary artery fibrosis, severe hypertension, ESRD, dysphagia, fatigue, weight loss, and gastroesophageal reflux. Pulmonary hypertension, which may result from interstitial lung disease or vasculopathy, is a leading cause of death in systemic sclerosis and is associated with increased perioperative risk.[371]

The preoperative evaluation focuses on the organ systems in the manner outlined previously in the section on SLE, with special attention to evidence of pulmonary hypertension (see section on "Pulmonary Hypertension"). The history should evaluate for any evidence of pulmonary disease (e.g., cough, dyspnea) or cardiac disease (e.g., dyspnea, orthopnea, chest pain). Patients may develop limited mouth opening, limited neck mobility, poor dentition, and oropharyngeal lesions secondary to skin involvement. Careful airway evaluation and planning for airway management are essential in such individuals, especially because they may also be at high risk for aspiration secondary to gastroesophageal reflux. Dermal involvement, edema, and contractures may also make venous access and regional anesthesia technically challenging. Thus, it is helpful to discuss central venous access and possible awake fiberoptic intubation during the preoperative assessment; in some cases, consideration should be given to arranging for interventional radiology to place intravenous lines.

Patients with systemic sclerosis usually need an ECG, and blood sampling for CBC (especially if receiving immunosuppressant therapy) and creatinine concentration. A chest radiograph and PFTs can be useful if interstitial lung disease or pulmonary fibrosis is suspected. Echocardiography (i.e., right ventricular size, right ventricular function, estimated right ventricular systolic pressure) may be useful to screen patients with suspected pulmonary hypertension. Antihypertensive agents (including calcium channel blockers for Raynaud phenomenon) and immunosuppressant therapy should be continued.

Raynaud Phenomenon

Raynaud phenomenon is an exaggerated vascular response to cold or emotional stress that results in color changes of the digits (typical sequence is pallor to cyanosis to rubor).[373] It is classified as primary (termed *Raynaud disease*) or secondary (termed *Raynaud phenomenon*). Raynaud phenomenon is associated with connective tissue diseases, autoimmune disorders, drugs, and use of vibrating tools. Connective tissue diseases associated with Raynaud phenomenon include systemic sclerosis, Sjögren disease, SLE, and possibly rheumatoid arthritis. Raynaud phenomenon most often affects the hands, typically resulting in a sudden onset of cold digits with sharply demarcated pallor or cyanosis. Cutaneous vasospasm is also common in other sites, such as the face and ears, where it causes pain and numbness. Criteria for the diagnosis of Raynaud disease include symmetric episodic attacks, absence of PAD, absence of tissue injury (or gangrene), normal nail fold capillary examination, normal erythrocyte sedimentation rate, and negative antinuclear antibody test. Raynaud disease requires no special additional preoperative evaluation. Secondary Raynaud phenomenon should prompt an assessment for associated disease states. It is also important to distinguish Raynaud phenomenon from PAD, especially given the difference in associated comorbidities. Calcium channel blockers are useful treatments in many patients and should be continued in the perioperative period.

Inherited Connective Tissue Disorders

Ehlers-Danlos syndrome is a disorder of collagen synthesis. It consists of several subtypes that have various manifestations but are almost all characterized by joint hypermobility. Type IV disease is more serious because affected individuals may have vascular fragility and skin fragility, as well as predisposition to vascular rupture, visceral rupture, and pneumothorax. Patients with type VI Ehlers-Danlos syndrome have muscle weakness, scoliosis, ocular fragility, skin fragility, and osteopenia.

Marfan syndrome is characterized by tall stature, arachnodactyly (i.e., long digits), scoliosis, pectus excavatum, valvular disease (e.g., aortic insufficiency, mitral valve prolapse, mitral regurgitation), arrhythmias, and ascending aortic dilatation. These patients are at risk for aortic dissection. Ocular (e.g., ectopia lentis, strabismus, glaucoma) and pulmonary (e.g., spontaneous pneumothorax) complications can also occur.[374] Other manifestations include retrognathia and high arched palates. Careful auscultation for the diastolic murmur of aortic insufficiency is important (see Table 31.8). If such a murmur is detected, subsequent tests should include an echocardiogram and chest radiograph. The most distinguishing feature of osteogenesis imperfecta is the propensity for fractures from extremely fragile bones.

These patients may have blue sclerae, short stature, scoliosis, joint hypermobility, hearing loss, muscle weakness, mitral valve prolapse, aortic insufficiency, and platelet dysfunction. An ECG and echocardiogram are necessary if physical examination reveals a murmur. Epidermolysis bullosa is distinguished by blistering, skin fragility, and scarring caused by abnormal epidermal-dermal anchoring. Even noninvasive blood pressure measurement may cause skin blistering and breakdown in an affected individual.

Kyphoscoliosis

Kyphoscoliosis is a curvature of the spine in both lateral and posterior directions. It can involve the thoracic region, the lumbar region, or both. Kyphoscoliosis may occur alone or as a manifestation of other diseases (e.g., collagen vascular disorders, Marfan syndrome, neurofibromatosis, muscular dystrophies, cerebral palsy). Therefore, the preoperative evaluation should also focus on identifying any coexisting abnormalities. Severe thoracic deformity may cause cardiopulmonary compromise as a consequence of restrictive lung disease, pulmonary hypertension, heart failure, tracheobronchial compression, or cardiac compression. The history should focus on assessing cardiopulmonary symptoms. The ability of the patient to lie supine (to facilitate airway access and management) must also be determined. The physical examination should evaluate vital signs (including oxygen saturation), pulmonary system (rales, decreased air entry), and cardiovascular system (murmurs, additional heart sounds, edema, jugular venous distention). A CBC, as well as a blood type and screen, is required in any patient scheduled to undergo spine correction surgery for kyphoscoliosis. Additionally, an ECG and chest radiograph may be useful. If heart failure is suspected based on clinical evaluation, a preoperative echocardiogram should be performed. Any reversible lung disease or heart failure must be optimized preoperatively.

CANCERS AND TUMORS IN PREOPERATIVE PATIENTS

Patients With Cancer

Patients with cancer may have complications related to both the disease itself and its treatment (e.g., chemotherapy, radiation therapy). Typically, patients are aware of the side effects of their cancer treatments. It is helpful to ask them whether any unexpected complications occurred during treatment, or whether chemotherapy or radiation therapy had to be interrupted because of adverse effects. A hypercoagulable state is also common in cancer, particularly advanced disease, primary brain tumors, ovarian adenocarcinoma, pancreatic cancer, colon cancer, gastric cancer, lung cancer, prostate cancer, and kidney tumors. The risk of thromboembolic events is increased six-fold in patients with cancer, with active cancer accounting for 20% of new cases of thromboembolism.

The preoperative evaluation focuses on cardiac, pulmonary, neurologic, and hematologic systems. Previous head and neck irradiation may cause carotid artery disease, hypothyroidism, or difficulty with airway management. Auscultation for bruits, thyroid function tests, and carotid Doppler studies are therefore recommended. Mediastinal, chest wall, or left breast irradiation can cause pericarditis, conduction abnormalities, cardiomyopathy, valvular heart disease, and premature IHD (even in the absence of traditional cardiovascular risk factors).[375] Thus, younger patients with a history of radiation therapy should be assessed for cardiac symptoms and undergo an ECG—even if they may not otherwise be at risk for heart disease. Based on these initial results, stress testing and echocardiography may be indicated. Previous irradiation to the lungs, breast, or mediastinum may also cause radiation pneumonitis. In such individuals, an oxygen saturation measurement and chest radiograph may be required, with consideration for PFTs if appropriate.

Other important chemotherapy-associated side effects include cardiomyopathy with trastuzumab and anthracyclines (e.g., doxorubicin); pulmonary toxicity with bleomycin; nephrotoxicity with cisplatin; hemorrhagic cystitis with cyclophosphamide; and peripheral neuropathy with vincristine or cisplatin. Many chemotherapeutic agents are toxic to the bone marrow, and patients commonly exhibit preoperative anemia. Patients who received corticosteroids as part of their cancer treatment may be at risk for adrenal insufficiency. These individuals may require supplemental perioperative corticosteroids; details on patient selection for such therapy, as well as a suggested dosing regimen, are presented in the section on "Hypothalamic-Pituitary-Adrenal Disorders" and Table 31.15. Other chemotherapy drugs result in impaired postsurgical wound healing, especially antiangiogenic agents (e.g., bevacizumab, sunitinib, sorafenib, pazopanib, vandetanib, cabozantinib, axitinib). Consequently, elective major surgery should be scheduled after temporary discontinuation of these agents, whenever feasible. The time interval for preoperative discontinuation varies across these agents from 28 days (bevacizumab) to 1 week (sunitinib, sorafenib, pazopanib, vandetanib, cabozantinib) to 48 hours (axitinib). Based on the type of chemotherapy, an ECG, chest radiograph, and blood sampling for CBC, electrolyte concentrations, creatinine concentration, and liver function tests may be needed. In some cases, consideration may be given to delaying the surgical procedure to allow resolution of neutropenia and thrombocytopenia. In general, advance planning of blood component replacement (including type and screening in the preoperative clinic) can avoid delays on the day of surgery.

The direct effects of cancers depend on the specific organ systems involved. Issues pertaining to intracranial tumors are discussed in the section on "Central Nervous System Tumors". Bone and liver involvement with metastases can commonly occur in patients with breast, colorectal, lung, and head and neck tumors. These bony lesions can in turn cause hypercalcemia or pancytopenia. Head and neck tumors, and their associated therapy (e.g., surgery, radiation), may cause thyroid dysfunction and difficulty with airway management. Lung cancer can cause airway problems, compromised pulmonary function, or mediastinal masses (see section on "Mediastinal Masses"). In these cases, computed tomography scans of the head, neck, or chest may be indicated. Paraneoplastic syndromes can complicate almost any type of malignant disease but are most commonly seen with lung cancer. Typical manifestations of these syndromes include hypercalcemia, inappropriate ADH secretion, Lambert-Eaton syndrome, Cushing syndrome, and neuropathies.

Patients who are receiving opioids on a long-term basis for cancer pain are likely to require larger than usual doses of medication for postoperative pain control (see the later section on "Planning for Postoperative Pain Management"). On the day of surgery, these patients typically take their usual analgesic medications, with the exception of NSAIDs (which, if possible, should be stopped 2-3 days before surgery).

Mediastinal Masses

Tumors that may occur in the anterior mediastinal space include lymphomas, thymomas, teratomas, thyroid goiters, and metastatic tumors. Anterior mediastinal masses can obstruct the great vessels (i.e., aorta, pulmonary arteries, pulmonary vein, superior vena cava), heart, trachea, and bronchi. Patients may complain of dyspnea, dysphagia, stridor, wheezing, coughing (especially when recumbent), and orthopnea. Compression of the superior vena cava can result in superior vena cava syndrome, which is characterized by jugular venous distention as well as edema in the face, neck, chest, and upper extremities. Affected individuals may also develop increased intracranial pressure and airway compromise. Imaging of the chest (with computed tomography or MRI) and echocardiography are needed if airway, cardiac, or vascular compression is suspected. Flow-volume loops may also be useful to assess the location (extrathoracic vs. intrathoracic) and degree of airway obstruction. Patients with tracheobronchial, cardiac, or major vessel compression require special anesthetic precautions, including possible awake fiberoptic intubation.

Von Hippel–Lindau disease

von Hippel–Lindau disease is an autosomal dominant inherited disorder characterized by a variety of benign and malignant tumors. Associated tumors include hemangioblastomas, retinal angiomas, clear cell renal cell carcinomas, pheochromocytomas, and neuroendocrine tumors of the pancreas. During preoperative evaluation, the anesthesiologist should assess for symptoms suggestive of a pheochromocytoma or neuroendocrine tumor (see relevant sections of this Chapter), as well as evaluate the patient's renal function. Any further testing (e.g., electrolytes, ECG, creatinine, glucose) should be guided by findings from the initial clinical evaluation.

Carcinoid Tumors

Carcinoid tumors are rare neuroendocrine tumors that release mediators. They are associated with MEN type 1. These tumors typically occur in the gastrointestinal tract and are the most common neoplasms of the appendix; in addition, they can also occur in the pancreas and bronchi. Carcinoid syndrome is caused by vasoactive amines (e.g., serotonin, norepinephrine, histamine, dopamine), polypeptides (e.g., bradykinin, somatostatin, vasoactive intestinal peptide, glucagon), and prostaglandins released by the tumors. Typical manifestations include flushing, tachycardia, arrhythmias, diarrhea, malnutrition, bronchospasm, and carcinoid heart disease. Nonetheless, most patients are asymptomatic because the liver inactivates the bioactive products of carcinoid tumors. Consequently, patients with gastrointestinal carcinoid tumors have manifestations of carcinoid syndrome only if they have hepatic metastases. Carcinoid heart disease is characterized by endocardial fibrosis of pulmonic and tricuspid valves. Affected individuals may then develop tricuspid regurgitation, pulmonic stenosis, pulmonic regurgitation, right-sided heart failure, peripheral edema, and hepatomegaly. They may also develop *carcinoid crisis*, which is associated with profound flushing, bronchospasm, tachycardia, and hemodynamic instability. These life-threatening episodes can occur with induction of anesthesia, intraoperative handling of a tumor, or other invasive procedure on a tumor (e.g., tumor embolization).[376]

The preoperative clinical evaluation should focus on dyspnea, orthopnea, wheezing, edema, arrhythmias, and murmurs; subsequent diagnostic tests are guided by the initial assessment. Patients with chronic diarrhea need measurement of electrolyte and creatinine concentrations. Patients with cardiac involvement must have an ECG and echocardiogram. Malnourished patients need an ECG, as well as measurement of electrolyte and albumin concentrations. Predictors of perioperative adverse events in these patients are carcinoid heart disease and elevated urinary 5-hydroxyindoleacetic acid concentrations.[377] The mainstay of pharmacologic treatment of carcinoid syndrome are somatostatin analogues, namely octreotide and lanreotide. Preoperative treatment with octreotide (300-500 µg intravenous or subcutaneously) helps mitigate the risks of intraoperative carcinoid crises.[378] An alternative approach for high-risk major procedures is to start a continuous intravenous 50 µg /hour infusion of octreotide 12 hours before surgery and continue it for at least 24 to 48 hours after surgery.[376]

Special Issues in Preoperative Evaluation

PSEUDOCHOLINESTERASE DEFICIENCY

A personal or family history of pseudocholinesterase, or butyrylcholinesterase, deficiency should be identified preoperatively (see Chapter 35). Pseudocholinesterase, which is found in the plasma, liver, pancreas, heart, and brain, is distinct from acetylcholinesterase, which is found in erythrocytes. Patients with an "allergy to succinylcholine" should be suspected of having either this disorder or malignant hyperthermia. Previous anesthetic records may help clarify an uncertain history. Additionally, inquiring whether the patient was intubated postoperatively, gravely ill, or in need of intensive care may be helpful.

Pseudocholinesterase activity may be permanently reduced because of abnormal genotypes, or transiently altered because of disease, drugs, pregnancy, or infancy. In patients with a history suggestive of pseudocholinesterase deficiency, recommended testing includes plasma cholinesterase activity, dibucaine number, and fluoride number. Plasma cholinesterase activity is a *quantitative* measure of enzyme activity, whereas the dibucaine number and fluoride number are *qualitative* measures. Plasma cholinesterase activity should not be confused with acetylcholinesterase activity, which is an assessment of erythrocyte cholinesterase. The *dibucaine number* represents the percentage inhibition of the enzyme by the local anesthetic dibucaine, and the fluoride number represents the percentage inhibition by fluoride. Normal individuals—who are homozygous for the wild-type gene—have a dibucaine number of 80 because their plasma cholinesterase is 80% inhibited by dibucaine. Individuals who are homozygous for the atypical genes have a dibucaine number of 20 (corresponding to 20% inhibition) and can be paralyzed for 4 to 8 hours after receiving succinylcholine. In heterozygous individuals who have a dibucaine number of 60 (corresponding to 60% inhibition), the duration of action of succinylcholine is prolonged by 50% to 100%. The combination of dibucaine number and plasma cholinesterase activity therefore differentiates genetic from acquired causes of prolonged apnea after succinylcholine administration. Patients with known or suspected pseudocholinesterase deficiency should be encouraged to obtain proper medical alert identification. Additionally, they should be educated that the enzyme also metabolizes ester-linked local anesthetics.

MALIGNANT HYPERTHERMIA

A known history or suggestive history (e.g., hyperthermia or rigidity during anesthesia) of malignant hyperthermia in a patient or family member must be clearly documented in the preoperative assessment. This information must also be communicated to the surgeon and eventual anesthesia provider—especially to ensure that appropriate arrangements are made preoperatively (see Chapter 35). Individuals who are genetically predisposed to malignant hyperthermia are asymptomatic until they are exposed to triggering agents. Certain neuromuscular diseases are also associated with elevated risks of malignant hyperthermia, including some muscular dystrophies (i.e., Duchenne, Becker, myotonic), King-Denborough syndrome, central core disease, periodic paralysis, osteogenesis imperfecta, myelomeningocele, and strabismus.

MORBIDLY OBESE PATIENTS

The morbidly obese patient presents special preoperative risks. Obesity is associated with several important comorbidities, including diabetes mellitus, hypertension, cardiovascular disease, CVD, cancer, OSA (see the earlier section on “Obstructive Sleep Apnea”), and poor functional capacity. Obese individuals are also at risk for NASH, which can result in abnormal liver function tests, liver fibrosis, and end-stage liver disease. In addition, patients with extreme obesity are at risk for right-sided heart failure and pulmonary hypertension. Such individuals can have obesity-hypoventilation syndrome (OHS), also known as Pickwickian syndrome. OHS is characterized by impaired central ventilatory drive and is distinct from OSA. It is associated with awake, chronic hypoxemia ($PaO_2 < 65$ mm Hg) without a diagnosis of COPD or primary lung disease. In the perioperative setting, obese patients experience higher rates of difficult bag-mask ventilation and difficult tracheal intubation.

The preoperative evaluation focuses on relevant coexisting diseases, airway, cardiopulmonary system, and vital signs (including pulse oximetry). When measuring blood pressure, the cuff should have a width that is approximately two thirds of the arm and a length that can adequately encircle the extremity. Assessment of neck circumference can also identify individuals at risk for difficulty with endotracheal intubation. It is also helpful to determine both actual body weight and ideal body weight. Determination of ideal body weight may be helpful in dose selection for certain medications (e.g., neuromuscular blockers),[379] and for determining optimal intraoperative mechanical ventilation settings. Treatments for obesity can have important perioperative implications. For example, drugs or other weight reduction methods (e.g., purging, diuretics, laxatives, gastric bypass procedures) may result in electrolyte abnormalities, vitamin deficiencies, malnutrition, anemia, and cardiopulmonary disorders. Two previously available antiobesity medications, fenfluramine and dexfenfluramine (both were withdrawn from the market in 1997), had significant cardiac side effects, including regurgitant valvular lesions and pulmonary hypertension. Any individual who was ever exposed to these drugs should undergo a cardiovascular evaluation, including an echocardiogram.

PATIENTS WITH TRANSPLANTED ORGANS

The number of patients with transplanted organs who require nontransplant surgical procedures increases yearly. During preoperative evaluation, these patients present special issues relating to transplant function, allograft denervation, immunosuppression, and other posttransplant physiologic and pharmacologic issues. Close interaction with the transplant team is one of the most important steps in the perioperative care of these patients. Clinicians performing the preoperative assessment should ensure that the transplant care providers are made aware of the upcoming procedure and are given an opportunity to make recommendations.

Some general preoperative considerations apply to all transplant recipients, as well as additional concerns based on the specific organ transplanted. In all transplant recipients, the level of function of the transplanted organ and the presence of any rejection should be evaluated. The dosage regimen of all immunosuppressant medications should be noted, and patients should be instructed to continue these medications perioperatively. However, these drugs can modify the pharmacology of many other agents administered during the perioperative period, as has been extensively summarized in the literature.[380,381] Patients should also be assessed for complications related to immunosuppressant therapy. These complications include the following: hyperglycemia and adrenal suppression (corticosteroids); increased risks of infection, hypertension, and renal insufficiency (corticosteroids, cyclosporine, tacrolimus); and myelosuppression causing anemia, thrombocytopenia, and leukopenia (azathioprine, sirolimus). Although transplant recipients are at increased risk for postoperative infections, no evidence indicates that higher doses of antibiotic prophylaxis provide added benefit. Instead, usual preoperative recommendations for antibiotic prophylaxis should be followed. Stress-associated adrenal insufficiency may occur in patients taking long-term corticosteroid therapy. Details on which patients warrant perioperative stress dose corticosteroids, as well as a suggested dosing regimen, are presented in the section on “Hypothalamic-Pituitary-Adrenal Disorders” and Table 31.15.

Cardiac evaluation is important in all transplant recipients because they are at increased risk for cardiovascular disease. The basis for this increased risk includes the underlying diseases that led to organ failure (e.g., diabetes mellitus, hypertension) and the potential for drug regimens, transplantation, and rejection episodes to create or worsen traditional cardiovascular risk factors. Preoperative renal function should also be assessed because long-term immunosuppressive regimens often lead to CKD. Although the effects of transplantation and immunosuppressive regimens on intravascular coagulation are controversial, thromboprophylaxis should be considered in all transplant recipients.

Kidney transplant recipients present some specific issues for preoperative evaluation. Despite the presence of a normal creatinine concentration, GFR in these individuals is generally decreased. This impairment in renal function predisposes these patients to electrolyte abnormalities and altered drug metabolism. Nephrotoxic drugs, such as NSAIDs and COX-2 inhibitors, should be avoided in all renal transplant recipients. In addition, their risk for cardiovascular disease is increased to approximately twice that of the general population. Careful preoperative cardiovascular evaluation is essential.

Successful liver transplantation usually resolves the hepatic and other end-organ effects of end-stage liver disease. Nonetheless, some pretransplant pulmonary problems may not resolve after transplantation, thus necessitating careful evaluation of pulmonary function. These disturbances can include hepatopulmonary syndrome, which involves hypoxemia from intrapulmonary vascular shunting. Other patients may continue to demonstrate ventilation-perfusion mismatch related to pulmonary effusions, ascites, or diaphragmatic dysfunction, as well as diffusion abnormalities resulting from interstitial pneumonitis or impaired hypoxic pulmonary vasoconstriction.

Following successful lung transplantation, recipients may require months to achieve peak pulmonary function. Compared with all other allografts, the transplanted lung is especially susceptible to infection and rejection as a result of its exposure to the external environment. Careful preoperative evaluation with PFTs should be considered in all lung transplant recipients, with postponement of elective surgery when allograft rejection or infection is suspected. Other perioperative considerations include airway hyperresponsiveness, loss of the cough reflex, and potential for injury to the airway anastomosis with intubation. These patients are also at increased risk for pulmonary edema, which has been attributed to disrupted lymphatic drainage in the transplanted lung.

Most issues relating to heart transplant recipients relate to the absence of autonomic innervation in the transplanted heart. This denervation has multiple physiologic effects, such as a higher than normal resting heart rate (from absence of vagal tone); the absence of cardiac baroreflexes; and the lack of response to carotid sinus massage, Valsalva maneuver, laryngoscopy, or tracheal intubation. Denervation also affects responses to medications; the allograft demonstrates a normal or augmented response to direct-acting drugs (e.g., epinephrine), a blunted response to indirect-acting agents (e.g., ephedrine), and no response to vagolytic agents. Chronic allograft rejection can manifest as accelerated IHD, and ventricular dysfunction (both systolic and diastolic). Because allograft denervation causes any myocardial ischemia to be silent, typical clinical manifestations include fatigue, ventricular dysrhythmias, heart failure, and ECG evidence of a silent myocardial infarction. Should preoperative evaluation raise clinical suspicions of worsening rejection, recent cardiac testing must be reviewed. Heart transplant recipients undergo routine periodic evaluation for IHD (cardiac stress testing or coronary angiography) and ventricular function (e.g., echocardiogram). The ECGs of these patients may reveal conduction abnormalities, and two P waves (a small nonconducted P wave from the native atria and a normal-sized conducted P wave from the donor atria). Many heart transplant recipients also require permanent pacemakers, and pacemaker function should be confirmed during the preoperative evaluation.

PATIENTS WITH ALLERGIES

The patient's preoperative evaluation record should carefully document any history of allergies and adverse drug reactions. True anaphylactic reactions should be distinguished from adverse side effects (e.g., nausea with opioid use), especially because a patient's definition of an allergy may differ significantly from the true clinical definition. In some cases, patients may incorrectly attribute previous perioperative difficulties to "allergies" to anesthetic or analgesic medications. The reported incidence of perioperative anaphylaxis is about 1 in 10,000 to procedures in large countrywide epidemiological studies, with consistent estimates based on studies from 2 different countries (France vs. United Kingdom) and time periods (2004 vs. 2016).[382,383] The overall incidence appears similar in these two epidemiological studies; however the common precipitating agents differ. In the older French study, the most common causes were neuromuscular blocking agents (58%), latex (20%), and antibiotics (13%).[383] Conversely, in the more recent United Kingdom study, the most common precipitating agents were antibiotics (53%), neuromuscular blocking agents (33%), and chlorhexidine (9%).[382] The mortality associated with an individual episode of anaphylaxis is about 4%,[384] but anaphylaxis accounts for up to 3% of perioperative deaths that are totally or partially related to anesthesia.[385] A careful history (including a review of records of prior allergic events and any associated laboratory tests) generally allows for avoidance of precipitating agents. In selected cases in which the clear diagnosis of a specific allergy is required to guide perioperative management, referral to an allergy specialist and possible skin testing (if the allergic reaction is believed to be immunoglobin E [IgE]-mediated) may be considered.

Allergic reactions to neuromuscular blocking drugs (NMBDs) are relatively more frequent in Europe as compared to North America. These differences have been attributed, in part, to the use of cough suppressants containing pholcodine in many European countries. Exposure to pholcodine is associated with development of IgE antibodies to NMBDs.[386] Confirmatory testing for an allergy to NMBDs can involve both skin testing and in-vitro assays for NMBD-specific IgE.

Although the rate of latex sensitization continues to increase, the development of better ways to identify at-risk patients has led to a decreased incidence of latex-induced anaphylaxis,[387] as evidenced by the absence of any latex-associated episodes in the recent epidemiological study from the United Kingdom.[382] The diagnosis of a latex allergy during preoperative evaluation is based on a careful history. Risk factors for latex allergy include a history of multiple surgeries, occupational exposure to latex (e.g., healthcare workers, food handlers), and an atopic history. This history may be supplemented with skin testing and latex-specific IgE antibody serology. When latex allergy is identified during the preoperative evaluation, the operative team should be notified in advance to ensure that all appropriate equipment is available. The ASA Task Force outlines detailed intraoperative considerations for these patients.[388] Among antibiotics, penicillins and cephalosporins are the most common causes of anaphylaxis. A small risk of cross-reactivity exists between penicillins and cephalosporins, but most of these reported reactions involve rashes, not anaphylaxis. Reported allergies to vancomycin should be distinguished from "red man syndrome." This histamine-induced side effect, which is associated with rapid injection of vancomycin, consists of flushing, pruritus, erythematous rash, and hypotension. With respect to other medications commonly encountered in the perioperative setting, anaphylactic reactions to amide local anesthetics are extremely rare. Most true anaphylactic reactions following exposure to ester local anesthetics do not involve an allergy to the local anesthetic, but rather to associated preservatives (e.g., *para*-aminobenzoic acid). Patients may incorrectly interpret adverse side effects from epinephrine in local anesthetic solutions as allergies, especially with dental procedures. Such reports should be carefully distinguished from true allergies. Similarly, true allergies to opioids are rare, with most reports of such "allergies" being simply opioid-related side effects, such as nausea and vomiting.

The scientific status of idiopathic environmental intolerance syndrome (formerly called multiple chemical sensitivity disorder) is very controversial. These individuals report chronic, diffuse, nonspecific symptoms with low levels of multiple chemical substances. Symptoms involve multiple organ systems and include fatigue, headache, memory loss, palpitations, and gastrointestinal symptoms. The symptoms are not generally accompanied by biologic test abnormalities or changes on physical examination, but they are frequently associated with psychiatric symptoms, notably depression and anxiety.[389] Preoperative evaluation of these patients can be extremely challenging because they have significant concerns about the multiple exposures involved during the perioperative period and the potential impact on their symptoms. No current recommendations are available on the perioperative care of these patients.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Acute infection with HIV causes a mononucleosis-like illness, which then progresses to chronic lymphadenopathy (lasting 3-5 years). Infection can culminate in cell-mediated immune deficiency characterized by opportunistic infections, malignant diseases (e.g., Kaposi sarcoma, non-Hodgkin lymphoma), and death (usually secondary from infections, wasting, or cancer). The prognosis of untreated HIV infection and acquired immunodeficiency syndrome (AIDS) is very poor.[390] Nonetheless, outcomes have now improved substantially in individuals compliant with highly active antiretroviral therapy.[391] Risk factors for HIV infection include sexual contact with an infected individual, bloodborne contamination, men who have sex with men, sexual workers, and those having contact with sexual workers. Most infection transmitted by blood exposure occurs in intravenous drug users, whereas infection through blood product transfusion in the United States is very rare (1 per 1.5-2 million blood transfusions). Mothers can transmit the disease to infants, which occurs usually during breastfeeding or delivery.[392] Many patients infected with HIV are unaware of their status.

HIV infection is a multisystem disease.[393] Cardiac complications include myocarditis, dilated cardiomyopathy, valvular disease, pulmonary hypertension, pericardial effusions, and cardiac tamponade. Pulmonary effects include lymphoid interstitial pneumonitis, as well as drug-resistant infections with *Pneumocystis jiroveci*, *Mycobacterium avium*, or *Mycobacterium tuberculosis*, cytomegalovirus, and *Cryptococcus*. Nervous system manifestations include central nervous system tumors, infections, aseptic meningitis, and AIDS-related dementia. Malignant diseases can occur, such as lymphomas, Kaposi sarcoma, and cervical cancer. These tumors can also have direct consequences for anesthetic management. For example, supraglottic or intraoral Kaposi sarcoma may interfere with ventilation and intubation, whereas non-Hodgkin lymphoma can cause mediastinal masses. Gastrointestinal manifestations include dysphagia, diarrhea, and esophagitis, which can in turn cause malnutrition, dehydration, and electrolyte imbalance. Renal complications include acute tubular necrosis, glomerulonephritis, renovascular disease, and HIV-associated nephropathy with nephritic syndrome. Antiretroviral medications used to treat HIV infection also have important side effects. The major classes of antiretroviral medications include nucleoside reverse transcriptase inhibitors (e.g., lamivudine, zidovudine, tenofovir, abacavir), nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine, efavirenz, rilpivirine), protease inhibitors (e.g., atazanavir, darunavir, lopinavir, fosamprenavir, saquinavir), attachment inhibitors (e.g., maraviroc), and integrase strand transfer inhibitors (e.g., raltegravir).[394] Side effects of relevance to anesthesiologists include lactic acidosis (nucleoside reverse transcriptase inhibitors), hepatotoxicity (nucleoside reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors, protease inhibitors), hyperlipidemia (protease inhibitors), insulin resistance (protease inhibitors), premature IHD (protease inhibitors),[395] cardiac conduction abnormalities (protease inhibitors), and bone marrow suppression (all classes).

If the preoperative evaluation of a relatively young, otherwise healthy individual elicits a history of thrush, fever of unknown origin, chronic diarrhea, lymphadenopathy, or herpes zoster in more than one dermatome, these findings should raise concern of undiagnosed HIV infection. In these cases, the enzyme-linked immunosorbent assay (ELISA) is the primary initial screening test. It demonstrates very high sensitivity exceeding 99% but yields a high number of false-positive results. The Western blot technique is used as the confirmatory test following an initial positive ELISA result. Patients with known HIV infection frequently require further evaluation, including an ECG, a chest radiograph, and blood sampling for CBC, electrolyte concentration, creatinine concentration, and liver function tests. If the patient shows evidence of malnourishment or nephrotic syndrome, further blood tests for albumin, total protein, and magnesium concentrations may be beneficial. The patient's perioperative prognosis may be estimated based on the CD4 lymphocyte count and viral load, which reflect the patient's immunologic status during the previous 3 months. In general, rates of postoperative complications and mortality are higher among patients with CD4 counts lower than 200 cells/mm^3 and viral loads greater than 10,000 copies/mL.[396,397] Patients' antiretroviral therapy must be continued through the perioperative period.

PATIENTS WITH A HISTORY OF SUBSTANCE ABUSE

A patient with a history of current or previous alcohol or drug addiction presents special challenges for the perioperative team. The lifetime prevalence of these addictions is significant; for example, about 14% of the United States population suffers from alcohol addiction.[398] In a suggested classification system, abused drugs can be categorized as central nervous system depressants (e.g., opioids, alcohol, sedatives, hypnotics), stimulants (e.g., cocaine, amphetamines), and other psychotropic substances (e.g., cannabis).[399] Importantly, many addicts are polysubstance abusers. Thresholds for defining high-risk alcohol consumption are 5 or more standard drinks in a day (>14 drinks per week on average) for males under 65 years of age, and 4 or more standard drinks in a day (>7 drinks per week on average) for all females and males 65 or more years of age. Addictive disease should be considered *permanent* even in patients who have had long periods of abstinence. Some patients in the process of recovery from addiction may be receiving specific medications to maintain recovery. For example, previous opioid abusers may be receiving methadone (long-acting opioid agonist), buprenorphine (partial μ-agonist), or naltrexone (opioid antagonist).

Substance abuse disorders are risk factors for poor outcomes in the perioperative setting. For example, individuals with histories of alcohol misuse experience elevated rates of postoperative complications.[72,400-402] In addition, they are at risk for postoperative withdrawal, acute intoxication, and altered tolerance of anesthetic or opioid medications. Consequently, it is worthwhile to incorporate screening for substance abuse disorders into the preoperative evaluation. Several simple validated screening questionnaires for alcohol abuse disorders are available, including the four-item CAGE questionnaire,[403] the three-item AUDIT-C questionnaire,[404] and the U.S. National Institute on Alcohol Abuse and Alcoholism 2- and 4-question tests (NIAAA-2Q/4Q).[405] These screening tools appear to be more sensitive when administered through a computer-based self-assessment questionnaire than during an in-person interview with a nurse or anesthesiologist.[406] The accuracy of these questionnaires can be further augmented with additional screening laboratory tests, namely gamma gluteryl transferase and carbohydrate-deficient transferrin.[6,407] The preoperative evaluation is also an opportunity to obtain a detailed history of known addiction (drug type, routes of administration) and recovery (periods of abstinence, pharmacotherapy for addiction). The dosage of any pharmacotherapy should be documented and verified. Patients in recovery may also have heightened anxiety regarding upcoming surgical procedures because of concerns about relapse into addiction, and inadequate pain treatment (given their history of addiction). Such concerns may be appropriate. Patients receiving opioid substitution therapy do experience normal pain responses to nociceptive stimuli but require additional analgesia for control of postprocedural pain.[408] These patients should therefore be reassured that anxiety and pain will be adequately treated. The clinicians performing preoperative evaluation may have prejudicial attitudes and lack the educational background to formulate appropriate perioperative pain management plans. For example, pain medication may be under dosed and inappropriately restricted because of concerns about provoking relapses. Early involvement of the acute pain service and addiction specialists to assist in the management of these at-risk patients may be helpful.

The preoperative period should be used to develop appropriate management plans based on the types of abused drugs. All pertinent preoperative information and management plans should be transmitted to members of the perioperative team. Individuals addicted to alcohol, sedatives, or hypnotics may require stabilization with benzodiazepines, whereas heroin addicts may require substitution with methadone. It is important to document the dosage of opioids consumed by individuals abusing these drugs, especially to help guide postoperative pain management. To avoid inadequate analgesia (which could potentially activate addiction) in these patients, the preoperative evaluation should be used to discuss and plan the optimal use of nonopioid analgesics and regional techniques. Patients actively abusing cocaine and amphetamines are at especially high risk during anesthesia because of the potential for intraoperative hemodynamic instability. Urine testing may be helpful to rule out abused substances in such patients, but the results should be interpreted based on drug pharmacokinetics. For example, the half-life of cocaine is about 1.5 hours but its inactive metabolites may still be detectable in the urine for 14 days after consumption.[409] A history of intravenous drug use should prompt an evaluation for cardiovascular, pulmonary, neurologic, and infectious complications such as endocarditis, abscesses, osteomyelitis, hepatitis, and HIV infection. Opioid (including heroin) users have a tolerance to narcotics. Patients with alcoholism are at risk for delirium tremens, a potentially life-threatening form of withdrawal characterized by autonomic instability and hyperpyrexia. These patients may also have liver disease (alcoholic hepatitis, cirrhosis, portal hypertension, end-stage liver disease), alcohol-induced cardiomyopathy, arrhythmias, seizures, neuropathies, dementia, Wernicke-Korsakoff syndrome (ataxia and cognitive dysfunction secondary to thiamine deficiency), macrocytic anemia, and coagulopathies (from hepatic dysfunction or vitamin K deficiency). Cocaine and amphetamine addicts can develop cerebrovascular accidents, cardiomyopathy, and arrhythmias. Additionally, cocaine and amphetamines inhibit the uptake of sympathomimetic neurotransmitters, thereby increasing risks for hypertension, tachycardia, paranoia, anxiety, seizures, and myocardial ischemia. Long-term use can result in ventricular hypertrophy, myocardial infarction, and nasal septal perforation. Solvents can cause cardiac dysrhythmias, pulmonary edema, cerebral edema, diffuse cortical atrophy, and hepatic failure. Hallucinogens, such as lysergic acid diethylamide, can cause autonomic dysregulation and paranoia. Ecstasy, or more specifically 3,4-methylenedioxymethamphetamine, can cause excessive thirst that results in hyponatremia, pulmonary edema, or cerebral edema. Acute marijuana use can cause tachycardia, vasodilatation, and increased cardiac output. The risk of pulmonary complications in patients who smoke marijuana is similar to that of individuals who smoke tobacco.[410]

During the preoperative evaluation interview, patients who abuse alcohol or drugs may not give a reliable history. The subsequent physical examination should include careful measurement of vital signs, including temperature. For example, cocaine and amphetamines may cause hypertension and tachycardia, whereas acute opioid use may result in a slow respiratory rate. Acute opioid use may also manifest as lethargy and pinpoint pupils, and recent alcohol consumption can often be detected by smell. Especially in individuals suspected of being intravenous drug abusers, it is important to examine venous access sites for signs of abscesses and infections. In addition, careful auscultation for murmurs is essential because of the risk of bacterial endocarditis. Cocaine or alcohol abusers can also exhibit findings in their cardiovascular examination consistent with heart failure or arrhythmias. Long-term alcohol abuse may manifest with physical findings of chronic liver disease. In addition to identifying the presence of substance abuse and its related complications, clinicians should ascertain whether, and for how long, patients can stop consuming alcohol or addictive drugs. If patients do stop consumption occasionally, it is especially important to determine what complications, if any, occur. When an alcoholic patient reports previously interrupting drinking for several days, the interviewer should inquire whether agitation, seizures, delirium tremens, or other signs of withdrawal developed. Any testing is largely informed by findings on the preoperative clinical evaluation, as well as the specific drug being abused. For example, an ECG may be warranted to assess for previous myocardial infarction in an individual with a history of cocaine abuse or in an individual receiving methadone (which prolongs the QT interval).

Ideally, patients with drug or alcohol dependence should be drug free well before elective surgical procedures. The availability of randomized trial data is limited and suggest that preoperative alcohol cessation programs can help prevent postoperative complications.[411] Preanesthesia clinic staff should therefore be prepared to refer patients to addiction specialists or to prescribe medications to prevent withdrawal in the preoperative period if patients agree to abstinence. For example, benzodiazepines can be useful in preventing or treating alcohol withdrawal symptoms.

Some medications used to manage withdrawal or facilitate recovery have specific perioperative considerations.[412] Patients taking methadone should continue maintenance doses in the perioperative period. Patients who are taking disulfiram because of a history of alcohol abuse may have an altered response to sympathomimetic drugs; some authors therefore suggest that disulfiram be discontinued 10 days before the surgical procedure.[412] If disulfiram is continued, users can experience flushing, nausea, and tachycardia in response to small amounts of alcohol, such as amounts encountered in skin preparations or medications. For patients taking naltrexone for a history of alcohol abuse, consideration should be given to discontinuing it 3 days preoperatively.[412] Naltrexone alters responses to opioid analgesics and may make postoperative pain management very challenging. Buprenorphine-containing medications (i.e., Suboxone), which are used to treat opioid addiction (as well as chronic pain), also alter responses to opioid analgesics. In the case of relatively minor surgery with minimal levels of anticipated postoperative pain, it is reasonable to continue buprenorphine perioperatively and maximize the use of nonopioid analgesic approaches (e.g., regional anesthesia, NSAIDs). In other cases, the perioperative management of buprenorphine should be coordinated with the patient's addiction specialist.

BREASTFEEDING PATIENTS

There are limited data to help guide recommendations for the safety of anesthetics and medications in babies of breastfeeding mothers who receive these agents. For elective surgery, women should be advised to pump and store milk preoperatively; this milk can be used in the first 24 hours after anesthesia administration, or for the duration of breast milk exposure to potentially harmful agents. The mother should discard milk produced within the first 24 hours after anesthesia, and then generally resume breastfeeding after this period. Very young or premature babies, especially those susceptible to apnea, may be at risk if the mothers continue to take opioid or sedating drugs. Mothers should be advised to discuss the safety of breastfeeding while taking medications with their child's pediatrician.

PATIENTS WITH DO NOT RESUSCITATE ORDERS

Some patients scheduled for procedures have advance directives or a do-not-resuscitate (DNR) status.[413] The ASA adopted guidelines for the care of these patients and updated them in 2013 (Box 31.14).[414] Frequently, in circumstances with DNR orders, care providers are focused on a procedure-directed approach (i.e., do not intubate, do not administer resuscitative drugs). This approach is problematic in the perioperative period because much of anesthesia care involves such procedures. Within the context of anesthesia care, a better approach is to discuss DNR status in a goal-directed approach (i.e., from the perspective of the patient's values and objectives, such as quality-of-life concerns).[415] The ideal time to have this emotional and complex discussion is during the preoperative evaluation. Short discussions in the preoperative clinic have been shown to foster dialogue among patients, their proxies, and physicians regarding advance directives concerning end-of-life care, as demonstrated by a randomized trial of patients at a preoperative evaluation clinic.[416] In this trial, individuals who received the information session were significantly more likely to complete a durable power-of-attorney (27%

BOX 31.14 **Do-Not-Resuscitate Orders in the Perioperative Period**

Policies automatically suspending DNR orders or other directives that limit treatment before procedures involving anesthetic care may not sufficiently address a patient's rights to self-determination in a responsible and ethical manner. Such policies, if they exist, should be reviewed and revised, as necessary, to reflect the content of these guidelines.

1. *Full Attempt at Resuscitation*: The patient or designated surrogate may request the full suspension of existing directives during the anesthetic and immediate postoperative period, thereby consenting to the use of any resuscitation procedures that may be appropriate to treat clinical events that occur during this time.
2. *Limited Attempt at Resuscitation Defined With Regard to Specific Procedures*: The patient or designated surrogate may elect to continue to refuse certain specific resuscitation procedures (for example, chest compressions, defibrillation or tracheal intubation). The anesthesiologist should inform the patient or designated surrogate about which procedures are (1) essential to the success of the anesthesia and the proposed procedure, and (2) which procedures are not essential and may be refused.
3. *Limited Attempt at Resuscitation Defined With Regard to the Patient's Goals and Values*: The patient or designated surrogate may allow the anesthesiologist and surgical team to use clinical judgment in determining which resuscitation procedures are appropriate in the context of the situation and the patient's stated goals and values. For example, some patients may want full resuscitation procedures to be used to manage adverse clinical events that are believed to be quickly and easily reversible, but to refrain from treatment for conditions that are likely to result in permanent sequelae, such as neurologic impairment or unwanted dependence upon life-sustaining technology.

DNR, Do-not-resuscitate.

Modified from Committee on Ethics, American Society of Anesthesiologists: Ethical guidelines for the anesthesia care of patients with do-not-resuscitate orders or other directives that limit treatment, 2013. Available at http://www.asahq.org/For-Members/Standards-Guidelines-and-Statements.aspx.

vs. 10%) and discuss end-of-life care with their proxy decision makers (87% vs. 66%).

Preoperative Laboratory and Diagnostic Studies

The value of preoperative diagnostic testing is a central issue in delivering cost-effective health care to surgical patients. The role of preoperative testing to screen for disease and evaluate patients' fitness for surgery has been extensively studied. This research has largely concluded that routine preoperative testing in all surgical patients (i.e., without consideration for their demographics or comorbidities) cannot be justified. Routine preoperative testing in asymptomatic healthy patients has very poor diagnostic yield, provides little to no additional prognostic information, and has not shown any beneficial effect on outcomes.[274,417-420] Unnecessary testing is also expensive, and may lead to costly evaluation of borderline or false-positive test abnormalities. Aside from potentially causing operating room delays or cancellations, these unnecessary follow-up tests may pose risks to patients that are attributable to follow-up tests and any associated interventions. Therefore, the targeting of testing in appropriate patients has both clinical and economic benefits. At some hospitals where surgeons and primary care physicians order all preoperative tests, the common practice has been to order tests without any diagnostic focus, other than speculation that the anesthesiologist may "require them" for surgery to proceed without delay or cancellation. Other justifications offered for nonselective ordering of tests include routine screening for disease states, establishment of a diagnostic baseline, personal habit (e.g., "standard" testing checklist for all patients), physician reassurance, and a perceived medicolegal necessity "not to miss anything." This pattern of practice has led to a plethora of preoperative testing practices that are costly, highly variable across hospitals, and largely unrelated to patients' perioperative risk profiles.[421-423] For example, in 2011, almost half of Medicare beneficiaries (aged ≥ 65 years) in the United States underwent preoperative laboratory testing before cataract surgery, which is considered a very low-risk procedure.[423]

Preoperative diagnostic tests should be selectively ordered based on the patient's medical history, planned surgery, and expected degree of intraoperative blood loss. Testing should be for the detection of specific clinical indications that may increase perioperative risk. Randomized trials have demonstrated that such a shift in strategy from nonselective to selective preoperative testing in low-risk surgical procedures can reduce costs while preserving patients' safety.[418,419] As experts in perioperative medicine, anesthesiologists are in a unique position to appropriately select the preoperative laboratory tests needed to guide perioperative care. Indeed, anesthesiologist-led preoperative evaluation has been shown to result in more selective ordering of laboratory tests than evaluation led by surgeons or primary care physicians.[14-17] Thus, by educating and providing specific guidance to surgeons and other physician specialists on the appropriate ordering of preoperative tests, anesthesiologists can expedite patient care, reduce healthcare costs, and improve the delivery of perioperative medicine.

A framework for ordering preoperative diagnostic tests based on patients' medical history is presented in Table 31.18. These disease-specific recommendations are not intended as absolute, especially since many hospitals and regional jurisdictions (e.g., Ontario Pre-Operative Testing Grid)[424] have developed their own preoperative testing recommendations. In addition, the NICE in the United Kingdom published updated 2016 guidelines for preoperative testing following an extensive systematic review of the literature.[274] The NICE guidelines consider both patients' preoperative medical status and the extensiveness of the planned surgery to determine when preoperative testing is warranted. In these guidelines, surgical procedures are graded as minor (e.g., skin lesion excision), intermediate (e.g., inguinal hernia repair, varicose vein excision, tonsillectomy, knee arthroscopy), and major (e.g., total abdominal hysterectomy, transurethral prostate resection, lumbar spine discectomy, thyroidectomy, total joint replacement, lung operations, colon resection, radical neck dissection). Although the most recent 2012 ASA "Practice Advisory for Preanesthesia Evaluation" does recommend against routine preoperative testing,[5] it does

not make explicit recommendations about which tests should be ordered for specific clinical conditions. The practice advisory states that the indications for testing should be "*based on information obtained from medical records, patient interview, physical examination, and type and invasiveness of the planned procedure.*" In addition, it describes patient-related and surgery-related factors that anesthesiologists should consider when deciding whether to order a specific laboratory test.[5] Conversely, the updated 2018 ESA guidelines on preoperative evaluation do make some specific recommendations for when preoperative laboratory testing should be performed.[6]

The following subsections discuss specific preoperative laboratory tests. In general, testing does not have to be repeated during the preoperative evaluation of healthy patients (i.e., ASA-PS class 1 or 2) if similar testing has already been performed within the 2 months preceding surgery and there has been no major interval change in the patient's medical status (e.g., recent chemotherapy).[425]

COMPLETE BLOOD COUNT, HEMOGLOBIN, AND HEMATOCRIT

The proposed surgery, associated potential blood loss, and individualized patient-level clinical indications should determine the requirement for a preoperative CBC. Typical clinical indications include a history of increased bleeding, hematologic disorders, CKD, chronic liver disease, recent chemotherapy or radiation treatment, corticosteroid therapy, anticoagulant therapy, and poor nutritional status. The NICE guidelines recommend routine CBC testing only in ASA-PS class 3 or 4 patients undergoing intermediate grade procedures, and all patients undergoing major procedures.[274]

RENAL FUNCTION TESTING

Renal function tests assess renal tubular function and glomerular filtration. Primary clinical indications include diabetes mellitus, hypertension, cardiac disease, potential dehydration (e.g., vomiting, diarrhea), anorexia, bulimia, fluid overload states (e.g., heart rate, ascites), known renal disease, liver disease, relevant recent chemotherapy (e.g., cisplatin, carboplatin), and renal transplantation. The NICE guidelines recommend routine renal function testing in ASA-PS class 3 or 4 patients undergoing intermediate procedures, and ASA-PS class 2, 3, or 4 patients undergoing major procedures.[274] If patients are deemed to be at risk for perioperative AKI, testing may also be considered in ASA-PS class 3 or 4 patients undergoing minor procedures, and ASA-PS class 2 patients undergoing intermediate procedures.[274]

LIVER FUNCTION TESTING

The ordering of liver function tests should be based on a history of liver injury and physical examination findings. Primary clinical indications include a history of hepatitis (viral, alcohol, drug-induced, autoimmune), jaundice, cirrhosis, portal hypertension, biliary disease, gallbladder disease, hepatotoxic drug exposure, tumor involvement of the liver, and bleeding disorders.

COAGULATION TESTING

Routine preoperative coagulation testing is not indicated (even in patients undergoing regional procedures) unless a known or suspected coagulopathy is identified on preoperative evaluation. Primary clinical indications for testing include a known bleeding disorder, hepatic disease, and anticoagulant use.[5] The 2016 NICE guidelines state that coagulation testing should only be considered in patients who are (1) ASA-PS class 3 or 4; (2) undergoing intermediate, major, or complex surgical procedures; and (3) known to take anticoagulant medications or have chronic liver disease.[274]

URINALYSIS

There is no indication for routine preoperative urinalysis.[274] Primary clinical indications include a suspected urinary tract infection and unexplained fever or chills.

PREGNANCY TEST

Pregnancy testing is often determined by hospital-specific protocols. It can also be based on clinical indications such as sexual activity, birth control use, and date of the last menstrual period. Another important factor that should be considered is the potential for the planned surgical procedure harming a fetus, based on direct injury (e.g., uterine surgery), reduction in blood flow (e.g., major cardiac or vascular surgery), and exposure to teratogenic agents (e.g., x-rays). The 2012 ASA "Practice Advisory for Preanesthesia Evaluation" suggests offering pregnancy testing to female patients of childbearing age when the result would alter the patient's management. It also recommends that informed consent be obtained for such testing, or that there be a full discussion of the risks, benefits, and alternatives related to preoperative pregnancy testing. The NICE guidelines recommend that all women of childbearing potential be asked whether there is any possibility they could be pregnant, and that any women who could possibly be pregnant be made aware of the risks of anesthesia and surgery to a fetus. The guidelines also recommend documenting all discussions about whether or not to carry out pregnancy testing, and to conduct pregnancy testing with patient consent if there is any doubt about pregnancy status.[274]

SICKLE CELL TEST

Individuals at risk for sickle cell disease include those of African, Caribbean, Eastern Mediterranean, and Middle Eastern origin. Even in at-risk populations, routine preoperative screening for sickle cell disease has a very low yield,[426] especially in regions with newborn screening programs for sickle cell disease.[427] Consistent with this evidence, 2016 NICE guidelines recommend against routine preoperative testing for sickle cell disease or sickle cell trait.[274]

A reasonable approach is to consider testing in *previously untested* patients who have at-risk ethnic backgrounds and clinical indicators. These indicators include patient-related (e.g., family history of sickle cell disease, sickle cell symptoms) and surgery-related (e.g., deliberate hypothermia, cardiopulmonary bypass, intrathoracic procedures, intraabdominal procedures, orthopedic procedures with tourniquet use) factors.

ELECTROCARDIOGRAM

The ECG can help detect a prior myocardial infarction, cardiac rhythm disturbances, ischemia, chamber hypertrophy, and electrolyte disorders. Nonetheless, when combined with usual clinical examination, the preoperative ECG may not provide additional prognostic information to identify individuals at risk for postoperative cardiac complications.[100] Primary clinical indications for preoperative ECGs include a history of IHD, hypertension, diabetes mellitus, heart failure, chest pain, palpitations, abnormal valvular murmurs, peripheral edema, syncope, dizziness, dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, and CVD. The 2014 ESC/ESA guidelines suggest preoperative ECGs in patients with risk factors for IHD or suspicious symptoms, especially if they are undergoing intermediate-risk or high-risk surgery.[9] The 2014 ACC/AHA guidelines are fairly consistent in that they support preoperative ECGs for patients who are undergoing intermediate-risk or high-risk surgery, and who have known IHD, significant arrhythmia, PAD, CVD, or other significant structural heart disease.[7] The guidelines also recommend against routine preoperative ECGs (see Box 31.2), especially in asymptomatic patients without known cardiovascular disease or risk factors.[7] The NICE guidelines recommend routine preoperative ECGs in ASA-PS class 3 or 4 patients undergoing intermediate grade procedures, and ASA-PS class 2, 3, or 4 patients undergoing major procedures.[274] If patients have cardiovascular disease, CKD, or diabetes mellitus, testing may also be considered in ASA-PS class 2 patients undergoing intermediate procedures.[274]

CHEST RADIOGRAPH

Routine preoperative chest radiographs do not provide prognostically important information for assessing perioperative risk.[428] Preoperative chest radiographs should therefore not be ordered routinely,[274] but rather selectively based on abnormalities identified by preoperative evaluation. These indications include advanced COPD, bullous lung disease, suspected pulmonary edema, suspected pneumonia, suspected mediastinal masses, and suspicious findings on physical examination (e.g., rales, tracheal deviation).

Preoperative Risk Assessment

A critical component of the preanesthesia evaluation is assessment of a patient's risk for undergoing anesthesia and surgery. This assessment improves patients' understanding of the inherent perioperative risks and better informs healthcare providers' clinical decision making. For example, these risk assessments might help identify individuals who warrant enhanced levels of postoperative monitoring, consideration for alternative nonoperative or less invasive treatment options for their underlying condition, or initiation of interventions intended to decrease perioperative risk. An anesthesiologist's designation of a surgical patient as being high-risk is clinically important. Specifically, when the initial preanesthesia evaluation deems that a patient is at unacceptably high risk for anesthesia and surgery, adherence to the anesthesiologist's recommendations for further perioperative management is associated with lower postoperative complication rates.[429] In addition, accurate risk assessments facilitate fairer comparisons of perioperative outcomes; specifically, estimates of patients' risks are required by statistical methods that adjust for case-mix differences across providers and hospitals.

TABLE 31.19 American Society of Anesthesiologists Physical Status Classification

Category*	Definition
ASA-PS 1	A normal, healthy patient
ASA-PS 2	A patient with mild systemic disease
ASA-PS 3	A patient with severe systemic disease
ASA-PS 4	A patient with severe systemic disease that is a constant threat to life
ASA-PS 5	A moribund patient who is not expected to survive without the operation
ASA-PS 6	A declared brain-dead patient whose organs are being removed for donor purposes

*The addition of "E" to the classification category indicates emergency surgery.

ASA-PS, American Society of Anesthesiologists physical status.

The most commonly used method by anesthesiologists to assess overall perioperative risk is the ASA-PS classification system (Table 31.19). This classification system, which was developed in 1941, was originally intended to facilitate collection and comparison of statistical data in anesthesia.[430] The ASA-PS classification system seeks to describe a patient's preoperative medical status, but it does not consider risks inherent to the planned surgical procedure. Although *not* intended to guide estimation of patients' risks for anesthesia and surgery, the ASA-PS is often used for this purpose, especially given its simplicity of use. Indeed, several studies have shown a correlation of ASA-PS scores with postoperative mortality and major complications.[97,218,431-433] An important limitation to the classification system is its inherent subjectivity; consequently, previous research has shown only fair to modest interrater agreement when different individuals attempt to assign an ASA-PS category to the same patient.[432,434-436]

In addition to patients' preoperative medical status, which is described by the ASA-PS system, the operative procedure is an important determinant of perioperative risk.[437-439] Overall perioperative risk is necessarily a function of both the risk associated with the specific operative procedure and the risk associated with a patient's underlying medical status. For example, ambulatory surgical procedures are very

TABLE 31.20 Johns Hopkins Surgery Risk Classification System

Category	Description
1	Minimal risk to the patient independent of anesthesia. Minimally invasive procedure with little or no blood loss. Procedures are often done in an office setting, with the operating room used principally for anesthesia and monitoring.
2	Minimal to moderately invasive procedure, with expected blood loss not exceeding 500 mL. Mild risk to patient independent of anesthesia.
3	Moderately to significantly invasive procedure, with expected blood loss of 500-1500 mL. Moderate risk to patient independent of anesthesia.
4	Highly invasive procedure, with expected blood loss exceeding 1500 mL. Major risk to patient independent of anesthesia.
5	Highly invasive procedure, with expected blood loss exceeding 1500 mL. Critical risk to patient independent of anesthesia. Usually requires postoperative critical care unit stay with invasive monitoring.

From Paternak LR, Johns A. Ambulatory gynaecological surgery: risk and assessment. *Best Pract Res Clin Obstet Gynaecol*. 2005;19:663–679.

safe with respect to risks of postoperative mortality and major adverse events,[440-442] as evidenced by a 7-day postoperative mortality rate of only 41 per 100,000 procedures in a large cohort of Medicare beneficiaries 65 years old or older.[440] Thus, although older patients with an increased burden of comorbidity do have increased relative risks of mortality and morbidity following ambulatory surgery, their *absolute* risks remain very low. Classification schemes have been proposed for assessing operative risk, such as the Johns Hopkins risk classification system (Table 31.20), elevated surgical risk category in the RCRI (see Table 31.5), and the strata employed by the ESA/ESC cardiovascular evaluation guidelines.[9,439] Importantly, individual operative procedures within broad categories (e.g., intraabdominal surgery) vary with respect to their perioperative risk.[107] As a consequence, there is a need to balance the desire to ensure that clinical prediction tools sufficiently capture the variability in operative risk across different procedures, against the need to ensure that these tools are sufficiently simple for straightforward clinical use.

Several commonly used and methodologically sound clinical indices can predict mortality and major morbidity after cardiac surgery with reasonable accuracy, such as the EuroSCORE,[443] Society of Thoracic Surgeons risk models,[444] and Cleveland Clinic AKI risk score.[269] A variety of prediction tools have also been developed for use in noncardiac surgery.[445] For example, the ACS NSQIP risk calculator is available on the Internet (http://riskcalculator.facs.org) and provides an estimate of risk based on patients' comorbidities and proposed surgical procedures.[32] High-quality validated indices have been developed for predicting specific major complications of noncardiac surgery, such as cardiovascular events (e.g., RCRI)[97,106] and respiratory complications (e.g., ARISCAT).[257,261] Other examples including the Surgical Risk Scale,[446] the Preoperative Score to Predict Postoperative Mortality (POSPOM),[99] and large multinational prospective epidemiologic studies of surgical patients (which included accurate capture of perioperative characteristics and outcomes),[77,78] will likely help lead to the development of other high-quality predictive indices.

ROLE OF SPECIALIZED TESTING IN PREOPERATIVE RISK ASSESSMENT

Based on an initial preoperative clinical evaluation, anesthesiologists may order subsequent specialized tests to help address diagnostic questions (e.g., "*Does this patient have aortic stenosis?*") or determine perioperative risk more accurately. Examples of such tests include noninvasive cardiac stress tests (see section on "Ischemic Heart Disease"), coronary angiography (see section on "Ischemic Heart Disease"), echocardiography, CPET, and PFTs (see section on "Pulmonary Disorders").

Resting echocardiography can provide information related to valvular lesions, pulmonary hypertension, fixed wall motion abnormalities, and ventricular function. Especially in cases of a suspicious murmur or other clinical indication, a preoperative echocardiogram can help diagnose prognostically important valvular or other cardiac lesions, such as aortic stenosis or pulmonary hypertension.[447,448] An echocardiogram can also identify fixed wall motion abnormalities consistent with a previous myocardial infarction. Although these findings can help support a diagnosis of IHD, fixed wall motion abnormalities are not themselves indicative of increased perioperative cardiac risk.[122] Similarly, while systolic ventricular dysfunction identified on echocardiography is associated with increased cardiac risk[161,162] this finding may not provide additional prognostic information when it is combined with routine preoperative clinical evaluation.[161] Thus, the overall role of echocardiography is to address focused *diagnostic* questions identified in usual clinical preoperative evaluation (e.g., suspicious systolic murmurs), not to provide important prognostic information pertaining to perioperative risk. Current guidelines therefore largely recommend preoperative echocardiography to assess dyspnea of unknown origin or recent altered clinical status in an individual with known heart failure (see Box 31.3).[7] In addition, repeat echocardiography is reasonable in clinically stable patients with known ventricular dysfunction who have not been tested in the previous year.[7] Conversely, routine preoperative echocardiography is discouraged.[7,8]

CPET is a noninvasive global assessment of exercise capacity; it involves a patient exercising on a bicycle or treadmill for 8 to 12 minutes while undergoing continuous measurement of respiratory gas exchange (i.e., oxygen uptake and carbon dioxide production).[449] Poor exercise capacity during CPET, based on either a low peak oxygen consumption or a low anaerobic threshold, is associated with increased risks of postoperative morbidity.[29,36,450] Thus, the test can help improve the accuracy of preoperative risk stratification. In some geographic settings,[451] CPET is a commonly used preoperative test. In these settings, it is used to aid preoperative risk assessment for major surgery, and to inform decisions on the appropriateness of planned major surgical procedures.

The role of PFTs for guiding preoperative assessment in the setting of specific comorbidities was discussed earlier in this chapter. These tests have an established and important role for assessing perioperative risk in lung resection surgery (see section on “Patients Scheduled for Lung Resection” and Chapter 53).[219] PFTs also play an important diagnostic role. For example, they help differentiate between pulmonary and cardiac causes of dyspnea of unknown origin. Aside from these specific circumstances, the *prognostic* value of preoperative PFTs is limited. Practice guidelines from the American College of Physicians recommend against routine preoperative spirometry for estimating risks for pulmonary complications after noncardiothoracic surgery.[10] Research has not found a consistent link between poor PFT results and increased risks for perioperative pulmonary complications, with older studies being generally limited by important methodologic flaws.[218] Furthermore, there does not seem to be a critical PFT threshold below which patients should not be offered surgery. For example, in a previous cohort study, individuals with severe obstructive findings (i.e., $FEV_1 < 50\%$ of predicted and FEV_1/FVC ratio < 0.7) had reasonably acceptable risks of postoperative death (5.6%) and respiratory failure (5.6%).[452]

Preoperative Medication Management

The patient’s comorbidities and planned procedure must inform medication management during the perioperative period. Some medications have beneficial effects during surgical procedures, whereas others may be detrimental. In some cases, abrupt *withdrawal* of medications can have a negative effect. Management of specific preoperative medications has been discussed in the previous sections of this chapter. These recommendations are outlined again in Box 31.15. Although issues pertaining to many drugs are covered in other sections of this chapter, several issues merit special mention.

NSAIDs have *reversible* antiplatelet effects; hence, once the drugs have been eliminated, platelet function returns to normal. Concomitant NSAID use does not appear to increase the risk of spinal hematoma with neuraxial anesthesia.[196] Preoperative discontinuation of NSAIDs may be of value in patients at risk for perioperative AKI. Typically, NSAIDs are discontinued 24 to 72 hours preoperatively. Earlier discontinuation does not increase safety, and it may be burdensome to many patients with significant arthritis or chronic pain. COX-2 inhibitors (e.g., celecoxib) have minimal effect on platelet function and can usually be continued in the perioperative period. However, the long-term COX-2 inhibitor use in the nonoperative setting does increase the risk of cardiac events, in comparison with placebo or naproxen.[453] Conversely, COX-2 inhibitors have a cardiac risk profile similar to that of ibuprofen or diclofenac.[453] In general, no clear evidence indicates increased

BOX 31.15 Preoperative Management of Medications

Instruct patients to take these medications with a small sip of water, even if fasting.

1. **Antihypertensive medications**
   Continue on the day of surgery, except for ACEIs and ARBs
2. **Cardiac medications (e.g., β-blockers, digoxin)**
   Continue on the day of surgery.
3. **Antidepressants, anxiolytics, and other psychiatric medications**
   Continue on the day of surgery.
4. **Thyroid medications**
   Continue on the day of surgery.
5. **Oral contraceptive pills**
   Continue on the day of surgery.
6. **Eye drops**
   Continue on the day of surgery.
7. **Heartburn or reflux medications**
   Continue on the day of surgery.
8. **Opioid medications**
   Continue on the day of surgery.
9. **Anticonvulsant medications**
   Continue on the day of surgery.
10. **Asthma medications**
    Continue on the day of surgery.
11. **Corticosteroids (oral and inhaled)**
    Continue on the day of surgery.
12. **Statins**
    Continue on the day of surgery.
13. **Aspirin**
    Continue aspirin in patients with prior percutaneous coronary intervention, high-grade IHD, and significant CVD. Otherwise, discontinue aspirin 3 days before surgery.
14. **$P2Y_{12}$ inhibitors (e.g., clopidogrel, ticagrelor, prasugrel, ticlopidine)**
    Patients having cataract surgery with topical or general anesthesia do not need to stop taking thienopyridines. If reversal of platelet inhibition is necessary, the time interval for discontinuing these medications before surgery is 5–7 days for clopidogrel, 5–7 days for ticagrelor, 7–10 days for prasugrel, and 10 days for ticlopidine. Do not discontinue $P2Y_{12}$ inhibitors in patients who have drug-eluting stents until they have completed 6 mo of dual antiplatelet therapy, unless patients, surgeons, and cardiologists have discussed the risks of discontinuation. The same applies to patients with bare metal stents until they have completed 1 month of dual antiplatelet therapy.
15. **Insulin**
    For all patients, discontinue all short-acting (e.g., regular) insulin on the day of surgery (unless insulin is administered by continuous pump). Patients with type 2 diabetes should take none, or up to one half of their dose of long-acting or combination (e.g., 70/30 preparations) insulin, on the day of surgery. Patients with type 1 diabetes should take a small amount (usually one third) of their usual morning long-acting insulin dose on the day of surgery. Patients with an insulin pump should continue their basal rate only.
16. **Topical medications (e.g., creams and ointments)**
    Discontinue on the day of surgery.
17. **Non-insulin antidiabetic medications**
    Discontinue on the day of surgery (exception: SGLT2 inhibitors should be discontinued 24 hours before elective surgery)
18. **Diuretics**
    Discontinue on the day of surgery (exception: thiazide diuretics taken for hypertension, which should be continued on the day of surgery).
19. **Sildenafil (Viagra) or similar drugs**
    Discontinue 24 h before surgery.
20. **COX-2 inhibitors**
    Continue on the day of surgery unless the surgeon is concerned about bone healing.
21. **Nonsteroidal antiinflammatory drugs**
    Discontinue 48 hours before the day of surgery.
22. **Warfarin (Coumadin)**
    Discontinue 5 days before surgery, except for patients having cataract surgery without a bulbar block.
23. **Monoamine oxidase inhibitors**
    Continue these medications and adjust the anesthesia plan accordingly.

ACEI, Angiotensin converting enzyme inhibitors; *ARB*, angiotensin receptor blocker; *COX-2*, cyclooxygenase-2; *CVD*, cerebrovascular disease; *IHD*, ischemic heart disease; *P2Y12*, adenosine diphosphate receptor; *SGLT2*, sodium-glucose cotransporter 2 inhibitors.

cardiac risk from *short-term* perioperative administration of COX-2 inhibitors. The exception is valdecoxib (now withdrawn from the market), which caused an excess of cardiac events in patients undergoing cardiac surgery.[454]

Postmenopausal hormone replacement therapies that contain estrogen increase the risk of thromboembolic events.[455] It may therefore be reasonable to discontinue these medications before operations. Estrogens must be stopped approximately 4 weeks preoperatively for coagulation function to return to baseline. Most modern oral contraceptives contain low doses of estrogen. Nonetheless, these medications are still associated with some elevation in thrombotic risk.[456] Since the risk of unanticipated pregnancy may outweigh the benefits of discontinuing oral contraceptives preoperatively, it is reasonable to continue oral contraceptives in most patients during the perioperative period. In patients who are deemed to be a high risk for postoperative VTE (see section on "Venous Thromboembolic Disorders"), consideration may be given to stopping oral contraceptives 4 weeks before surgery (and temporarily switching to other forms of contraception). This decision should be made collaboratively with the patient and must balance the risk of VTE versus the risk of unwanted pregnancy.

Most medications for psychiatric and psychological problems should be continued into the preoperative period. Thus, most antidepressants, antipsychotics, and benzodiazepines are best maintained to avoid exacerbations of symptoms. Historically, monoamine oxidase inhibitor (MAOI) antidepressants were discontinued preoperatively; however, elimination of the risks associated with many of these drugs required drug discontinuation at least 3 weeks before surgery. This long withdrawal period is specifically applied to MAOIs that cause irreversible inhibition of MAO. Some newer agents, such as moclobemide, cause reversible enzyme inhibition and have effects lasting less than 24 hours. Preoperative withdrawal of these drugs has potential risks. Specifically, case reports of suicides or severe depression following discontinuation of MAOIs have been reported. Thus, the safest approach may be to continue these drugs and adjust the anesthetic plan accordingly (e.g., avoid meperidine and indirect-acting vasopressors such as ephedrine). If this approach is taken, it is critical that details of a patient's MAOI use must be clearly communicated to healthcare providers on the day of surgery. Patients receiving tricyclic antidepressants require a preoperative ECG, given the potential for a prolonged QT interval. Because tricyclic antidepressants block the reuptake of norepinephrine and serotonin, high doses may also result in augmented responses to vasopressor drugs, with the potential for exaggerated hemodynamic changes. Patients taking lithium require evaluation of electrolyte and creatinine concentrations. Discontinuation of lithium has also been associated with suicide. Continued perioperative use of selective serotonin reuptake inhibitors (SSRIs) are associated with increased surgical bleeding,[457,458] whereas abrupt discontinuation of SSRIs can also cause dizziness, chills, muscle aches, and anxiety. Overall, it is still reasonable to continue SSRI perioperatively in most patients, aside from those undergoing procedures where bleeding could have significant postoperative sequalae (e.g., intracranial surgery).

Complementary and alternative medications may interact with anesthetic drugs, alter effects of prescription medications, and increase bleeding. In addition, many patients do not consider these drugs "medications," and may not list them among their medications unless specifically asked. The perioperative management of complementary and alternative medications is discussed in further detail in Chapter 33.

Planning for Anesthesia

PREOPERATIVE FASTING STATUS

The overarching goal of preoperative fasting recommendations has been to reduce the risk of pulmonary aspiration. The ASA published practice guidelines pertaining to preoperative fasting in nonlaboring individuals undergoing elective procedures.[459] The recommended fasting period following clear fluids for all patients is 2 hours. In general, the volume of liquid ingested is less important than the type of liquid ingested. For neonates and infants, the recommended fasting period is 4 hours following breast milk, and 6 hours following formula, non-human milk, and solids. For patients other than infants, a fasting period of 6 hours after a light meal is recommended; this period may have to be increased to 8 or more hours if the meal includes fried or fatty foods. In addition to implementing these fasting intervals, the guidelines recommend that the preoperative evaluation include assessment of the potential for difficult airway management, as well as factors that may increase the risk for aspiration (e.g., gastrointestinal motility disorders, diabetes).

PLANNING FOR POSTOPERATIVE PAIN MANAGEMENT

A preoperative evaluation should always include baseline pain assessment. Standardization of pain measurement is difficult because of the subjective nature of the variable. It is therefore helpful to incorporate standardized pain measurement scales into the preoperative evaluation process. The scales may either be single-dimension scales, such as visual analog and numeric rating scales, or multidimensional scales such as the McGill pain questionnaire,[460] and Modified Brief Pain Inventory—Short Form.[461] Although multidimensional scales are longer, they capture a broader range of important details. For example, the 9-item Modified Brief Pain Inventory—Short Form captures details on the pain intensity, pain location, adequacy of analgesic treatment, and pain-related interference in activities. Consistent use of the same scale during the perioperative episode of care allows comparison when reassessments are performed after surgery.

The preoperative evaluation provides an important opportunity to discuss and plan for the management of acute postoperative pain, for several reasons. First, adequacy of perioperative pain control is a frequent concern for patients during preoperative evaluation.[462,463] Second, intensive preoperative pain instructions may help improve postoperative pain control in surgical patients.[464] Third, preoperative anesthesia consultation is associated with improved patient acceptance of perioperative regional techniques,[19] which can help improve the quality of postoperative analgesia.[465] Fourth, preoperative evaluation facilitates planning the perioperative care of patients with chronic pain conditions, who often present significant challenges with respect to managing postoperative analgesia. Specific issues include their tolerance to usual doses of opioid analgesics and the potential for acute withdrawal reactions if they receive insufficient doses of opioids postoperatively. The preoperative consultation should therefore be used to carefully document their usual baseline opioid requirements (to ensure adequate postoperative dosing), facilitate early involvement of an acute pain service or transitional pain specialist,[466] encourage regional analgesic techniques, and plan adjunct analgesic medications (e.g., NSAIDs, gabapentin, pregabalin, clonidine). Patients with preexisting chronic pain should be encouraged to develop reasonable goals for adequacy of postoperative pain control. They should be informed that although care providers will do everything possible to maintain comfort postoperatively, patients should not expect to have no pain at all.

In general, patients should not be weaned from pain medications before surgery. If instructed by their surgeons to temporarily discontinue NSAIDs or COX-2 analgesics, they may have to be transitioned to alternative analgesics before surgery. Patients should be instructed to take their usual morning dose of pain medication, including continued use of any transdermal medications.

Regulatory Issues

Providers must be aware of various governmental regulatory requirements, which often differ by individual municipalities and countries. These requirements may be driven by quality regulations, such as those developed by The Joint Commission or by payment requirements as set by the Centers for Medicare and Medicaid Services (CMS) in the United States. For example, the CMS has determined that a comprehensive anesthesia evaluation can be done within 30 days, and a focused update is required within 48 hours of a procedure requiring anesthesia services. The evaluation should be performed by a practitioner qualified to provide anesthesia. At a minimum, the preanesthesia evaluation must include the following:

- Notation of anesthesia risk (e.g., ASA-PS classification)
- Review of the medical, anesthesia, drug, and allergy history
- Interview and examination of the patient
- Potential anesthesia problems (e.g., difficult airway, limited intravascular access)
- Additional evaluation, if deemed necessary (e.g., stress tests, specialist consultation)
- Development of a plan for anesthesia, including the type of medications for induction, maintenance, and postoperative care
- Discussion of the risks and benefits of anesthesia with the patient or the patient's representative

Preoperative Evaluation Clinic

Many anesthesiology groups and medical centers have developed preoperative evaluation programs and outpatient clinics, with the objectives of improving patient care and operating room efficiency.[14,22,467] Although these programs may differ with respect to staffing, structure, financial support, and daily operations, they all share a common goal of preventing delays, last-minute cancellations, and adverse patient outcomes that could have been addressed before the day of surgery.

The decision to develop a preoperative evaluation clinic depends on several key factors. They include the anticipated daily volume of surgical patients, the predominant level of medical acuity among these patients, the availability of clinic facilities, relevant patient demographics (e.g., average travel distances from patients' homes to the clinic), and requisite support from the anesthesia department, perioperative staff, and hospital administration. If the decision to implement a preoperative evaluation program is made, anesthesiologists must play a key role in its leadership and management. When this role is instead undertaken by other specialties, such as internal medicine, anesthesiologists' expertise in perioperative patient management often becomes secondary. This shift to a secondary role can result in interdepartmental conflicts concerning patients' preoperative evaluation, risk stratification, and fitness to proceed with anesthesia and surgery. These conflicts can, in turn, result in unplanned delays or cancellations of planned surgical procedures, despite the completion of an assessment in an outpatient preoperative evaluation clinic.

Such conflicts often relate to surgeons' interpretation of a nonanesthesia specialist's judgment that a patient is "cleared for surgery" as evidence that the patient is fit for anesthesia. Unfortunately, this "clearance" is frequently made with limited knowledge of factors critical to the responsible anesthesiologist in the operating room, such as current anesthesia practice and intraoperative patient management. Indeed, previous research has shown that preoperative histories, physical examinations, and assessments performed by medical specialists often fail to address specific anesthesia-related concerns.[468] As the specialist who makes the final determination of whether a patient is fit to proceed with anesthesia and surgery, the responsible anesthesiologist is a critical "end-user" of any assessment performed in a preoperative evaluation clinic. Consequently, a reliance on nonanesthesia specialists can result in preoperative assessments that are deemed inadequate by the responsible anesthesia providers and that lead to potential last-minute surgical delays and cancellations, with associated significant frustration among both patients and surgeons. Conversely, preoperative-to-intraoperative communication is likely significantly improved when anesthesiologists are responsible for most outpatient preanesthesia evaluations, as confirmed by previous studies showing fewer last-minute case cancellations,[14,20,22,469] shorter durations of hospitalization,[22,469,470] lower hospital costs,[469] and possibly reduced postoperative mortality,[471] with institution of anesthesia-led preoperative evaluation programs.

Awareness of the local hospital context is critical if a preoperative evaluation program is to have good outcomes. In a hospital with limited resources that has mostly healthy outpatient and same-day-admission surgical patients, the anesthesia group may be unable to evaluate all patients preoperatively in a clinic before the day of surgery. In this situation, the preoperative program must develop a means for accurate screening and triage of patients based on their current health status. An accurate triage process helps target the use of preoperative clinic visits only among selected higher-risk patients without compromising patients' quality of care and outcomes.[24] An example of such a triage process may involve having patients initially complete an anesthesia screening questionnaire in their surgeons' office. This questionnaire can be a Web-based online document or even a paper version that would then be faxed to the anesthesia group before the date of surgery. The anesthesia group can develop local context-specific screening questionnaires, or adopt published instruments developed for this purpose.[472,473] In the case of a patient with a questionable medical history, a telephone call by the anesthesiologist could clarify any issues of concern. This opportunity to review a patient's medical history before the day of surgery helps reduce unresolved or unexpected medical concerns on the day of surgery. It also helps determine whether a patient requires formal preoperative consultation in advance of the surgical procedure, as opposed to evaluation on the day of surgery itself.

Conversely, anesthesia departments at hospitals with many medically complex surgical patients may benefit from the establishment of a formal preoperative evaluation facility with multiple examination rooms, dedicated staffing, and a full-time operational system. The establishment of a successful preoperative evaluation clinic requires commitment, collaboration, and support from several hospital disciplines.[14] At a minimum, the departments of anesthesia, surgery, nursing, and hospital administration must agree that such a clinic has value for the hospital, and they must commit to support its operational goals.

COLLABORATION, COMMITMENT, AND TEAMWORK

The preoperative evaluation clinic is a partnership among the departments of anesthesia, surgery, nursing, and hospital administration to achieve common goals. This collaboration conveys the important theme that the new clinical program is an integrated enterprise that requires shared obligation, endeavor, and financial responsibility. Although these clinics are best led by anesthesiologists,[14,20,22,469] collaborative engagement with medical specialists (e.g., cardiologists, geriatricians) and hospitalists remains important to the success of any preoperative program. These nonanesthesia specialties provide unique expertise in the preoperative management of selected medically complex patients; furthermore, they can facilitate enhanced postoperative monitoring of high-risk patients through, for example, the comanagement model of postoperative care (see section on "Role of the Medical Consultant in Preoperative Evaluation").

Surgeons may be initially reluctant to send their patients to a newly established anesthesia-led preoperative evaluation clinic. This reluctance often stems from an unclear understanding of the benefits of outpatient preoperative anesthesia evaluation. Consequently, the surgeons' hesitation can be reduced by clearly identifying the specific advantages of an integrated anesthesia-led preoperative evaluation program. First, the proven benefits of anesthesiology-led preoperative evaluation should be highlighted.[14,20,22,469-471] Second, anesthesiologists should emphasize the important practical advantages of an integrated assessment of medically complex surgical patients. Specifically, when relevant medical concerns are identified before the surgical procedure, the preoperative program can acquire all relevant prior medical data, coordinate any additional workup or consultation, prearrange any required specialized postoperative monitoring, and discuss the case beforehand with the surgeon and responsible anesthesiologist. This approach ensures that when such a patient presents for the operation, the responsible anesthesia provider is satisfied to proceed with the surgical procedure, and the perioperative team has all required medical information to manage the patient optimally during the hospitalization. This integration of the preoperative evaluation with the entire perioperative episode of care is an integral component of the Perioperative Surgical Home model.[1]

Third, informal assurances should be made to the surgical services that, if a patient is managed by the preoperative evaluation program, surgery will proceed without cancellation or delay by the assigned anesthesiologist unless an intervening illness or adverse medical event occurs between the outpatient evaluation and the scheduled operation. Because cancellations and delays on the day of surgery can be a prominent source of aggravation for surgeons and patients, these informal assurances would be viewed as a key strength of the newly developed preoperative program. Such assurances depend heavily on the anesthesia department's addressing relevant clinical practice variations. Specifically, issues that are subject to important interpractitioner differences, such as what fasting blood glucose level or degree of preoperative hypertension would merit cancelling a surgical case, must be discussed to achieve a departmental consensus standard. The absence of consensus standards can lead to situations in which half the anesthesia providers may proceed with a higher-risk surgical case, whereas the other half would cancel it instead. Wide inconsistency in practice will foster a lack of support among surgeons and will lead to reluctance to have their patients evaluated. Such a preoperative evaluation program is unlikely to be successful.

ROLE OF THE MEDICAL CONSULTANT IN PREOPERATIVE EVALUATION

Use of preoperative medical consultation varies across hospitals, likely depending on the expertise in perioperative medicine among the clinicians performing preanesthesia assessments. Since exposure to preoperative evaluation is inadequate at many anesthesia residency programs,[474] some anesthesia departments may prefer that medical specialists take primary responsibility for preoperative evaluations at their centers. Conversely, when anesthesiologists involved with preoperative evaluation develop improved comfort with interpreting ECGs, cardiac stress tests, or other specialized tests, rates of medical consultations can be substantially reduced.[17]

Medical consultants have a clear role in the preoperative care of selected surgical patients. For example, these consultations can help manage unstable medical conditions (e.g., unstable angina), optimize poorly controlled medical diseases (e.g., asthma exacerbation), or facilitate clinically indicated diagnostic workups (e.g., coronary angiography following high-risk cardiac stress test results).

Preoperative consultation by medical specialists or hospitalists can also help facilitate postoperative comanagement by these same individuals.[475] The comanagement model for postoperative care of surgical patients is increasingly common,[476] although its benefits with respect to clinical outcomes and healthcare costs remain uncertain.[477-482] Multidisciplinary collaboration with medical consultants can be especially helpful for perioperative management of complex or uncommon medical disorders. Indeed, some clinical practice guidelines recommend such multidisciplinary team management for patients with known cardiac disease undergoing high-risk noncardiac surgery,[9] as well as patients with significant pulmonary hypertension or adult congenital heart disease undergoing noncardiac surgery.[7]

Despite these theoretical benefits, preoperative medical consultation has shown a variable effect on postoperative outcomes. A randomized trial of outpatient preoperative evaluation demonstrated fewer last-minute surgical cancellations but no difference in hospital length of stay, as well as an increase in consultations.[483] In other nonrandomized studies, medical consultation was associated with increases in specialized testing, costs, hospital length of stay, and mortality.[484,485] Conversely, a transition from an anesthesiologist-led to a hospitalist-led preoperative assessment clinic was associated with reduced hospital length of stay in high-risk patients,[486] while preoperative geriatric consultation was associated with improved postoperative 90-day outcomes (i.e., survival, hospital length of stay, need for supported discharge, hospital readmission) in elderly patients (≥65 years) undergoing major elective noncardiac surgery.[487] Potential reasons for this variable effect may be the absence of recommendations or new interventions resulting from many medical consultations,[488,489] as well as disagreements among medical specialists, anesthesiologists, and surgeons on the intended purpose of these consultations.[468] In addition, increased burden of comorbidity is a very small determinant of whether patients are referred for preoperative medical consultations,[490-492] a finding suggesting poor patient selection during referral to medical specialists. Thus, during preoperative evaluation, the anesthesiologist should ensure that any referrals to medical specialists before surgery involve appropriate matching of patient profiles to specialist expertise. For example, patients with high-risk IHD should be referred to a cardiologist, while frail elderly patients should be referred to a geriatrician.

STRUCTURES AND ACTIVITIES OF THE PREOPERATIVE EVALUATION CLINIC

The daily operations of a preoperative evaluation clinic vary based on the patient volume, the general level of medical complexity among surgical patients, the type of available clinic facilities, and staffing resources. Nonetheless, a general operational structure can be proposed based on examination of several preoperative clinic models currently in practice.

Centers with large surgical case volumes should have their patients formally scheduled in the clinic before the day of evaluation, to allow for medical records and relevant outside information to be acquired and collated. The surgeon's office should schedule this clinic appointment at the same time that it books the operating room case. To ensure timely patient access and flow through the facility, these appointments should be booked using an efficient clinic scheduling system. Ideally, appointments should be scheduled to allow sufficient time between the clinic visit and the scheduled surgical procedure, to facilitate any additional preoperative testing, consultations, or interventions. Some degree of flexibility in the clinic schedule is also needed, especially to accommodate patients who have urgent indications for surgery. One approach for incorporating some flexibility is to include a few open appointment slots in the daily clinic schedule that can be used as needed for last-minute patient referrals. Such flexibility is required for individuals residing in rural and remote areas, who have been reported to have reduced rates of access to preoperative evaluation clinic facilities.[493] Anesthesiologists at some centers have also adopted telemedicine technology (defined as healthcare delivery and sharing of medical knowledge over a distance using telecommunications systems)[494] so that patients residing at remote locations can undergo preanesthesia consultations without traveling long distances to the clinic.[495]

At the clinic, a clinician interviews and examines the patient, obtains historical medical information and outside records, and determines whether (and which) additional laboratory tests, ECGs, radiographs, or other diagnostic tests are required. Phlebotomy, ECG, and hospital admitting and insurance registration services are typically available in the preoperative clinic facility. The ECGs are assessed during the clinic visit itself, whereas laboratory test results are evaluated at the end of each clinic day, with follow-up of abnormal findings as needed. In this manner, significant abnormalities can be addressed immediately; thus, any required delays or cancellations of surgical cases can occur well in advance of the scheduled day of surgery. This centralization of multiple services is also a significant convenience for patients, who no longer have to visit multiple hospital locations to complete their preoperative requirements. This arrangement should also centralize all medical data relevant to the scheduled hospital admission into a single chart, which remains in the preoperative evaluation clinic area until the date of surgery. In addition to addressing medical aspects relevant to the scheduled surgery, the preoperative evaluation program plays an important role in educating surgical patients. Typically, both the clinician performing the preoperative assessment and a specifically trained nurse educator discuss the forthcoming perioperative process with each patient and family members. By increasing patients' awareness of important components pertaining to their scheduled hospital admission (e.g., analgesic options, risks of anesthesia), this education process can decrease patients' anxiety,[18] as well as increase their willingness to receive regional analgesia.[19] The types of clinicians who perform the preanesthesia assessment include anesthesiologists and specially trained nurse practitioners. Some authors have questioned whether the responsible anesthesiologist in the operating room would be satisfied with preanesthesia assessments performed by another individual.[496] Patients themselves often report a preference for having the same anesthesiologist in both the preoperative clinic and the operating room.[497] Nonetheless, it is simply not feasible for all patients in the preoperative clinic to be evaluated by their eventual anesthesia providers. Furthermore, a large Dutch cohort study of about 21,000 surgical patients demonstrated that responsible anesthesia providers were satisfied with 95% of outpatient preanesthesia assessments performed by other anesthesiologists or trained nurses.[498]

Preoperative programs must adopt several strategies to ensure that anesthesia providers in the operating room will be satisfied with the quality of outpatient preoperative assessments. First, the anesthesia department must develop consensus standards for determining when patients should have scheduled surgery cancelled for medical reasons. Second, the documentation required for all preanesthesia assessments in the clinic should be standardized. This standardization helps prevent situations in which an assessment does not contain information needed by the anesthesia provider in the operating room to determine a patient's fitness for surgery or to develop an anesthetic management plan. Some national anesthesiology groups have initiated work on consensus-based documentation standards for all preanesthesia assessments.[23] Strategies for improving the consistency of documentation across preanesthesia assessments include the use of checklists, as well as structured electronic or paper-based forms for documenting preanesthesia assessments. Third, all nurse practitioners or other nonanesthesia clinicians assessing patients in the clinic should undergo an intensive and ongoing education in preoperative assessment. Anesthesiologists with strong interest and expertise in preoperative evaluation should lead this education program. Previous research has shown that well-trained nurses do perform effectively in both screening and evaluating patients in preoperative clinics.[499-501]

IMPACT ON OPERATING ROOM EFFICIENCY AND OUTCOMES

Anesthesia-led preoperative assessment clinics have had positive impact on operating room efficiency and outcomes (see the earlier section "Goals and Benefits of Preanesthesia Evaluation"). The demonstrated benefits of these clinics include fewer case cancellations on the day of surgery,[14,20,22,469] shorter duration of hospitalization,[22,469,470] and a possible reduction in postoperative mortality.[471] Other mechanisms whereby preoperative evaluation clinics reduce healthcare costs include more selective ordering of preoperative laboratory tests and specialist referrals.[14,16,17] Thus, although preoperative evaluation programs do incur costs (e.g., facility development costs, staff salaries), they can still lead to an overall reduction in hospital costs as a result of these associated cost savings.[469]

PATIENT SATISFACTION WITH PREOPERATIVE EVALUATION CLINICS

In addition to addressing perioperative efficiencies and clinical outcomes, preoperative programs should also consider the experience and satisfaction of patients attending their clinics. During development of strategies to improve patient satisfaction, the underlying determinants of improved satisfaction should be considered. They include being assessed by the same anesthesiologist who will administer anesthesia in the operating room, shorter wait times in the clinic, and good quality of communication from the clinic staff.[497,502,503] Because it is simply not feasible to have all patients in the clinic seen by their eventual anesthesia providers, the major focus should be on improving wait times and the quality of communication. Changes in appointment booking systems,[504] process flows, and clinic operations can decrease wait times,[499] which in turn can substantially improve patients' satisfaction.[499] In addition, preoperative programs can ensure that patients receive an accurate estimate of average waiting times before their scheduled clinic visit, and use any encountered wait times to conduct other clinic-related activities (e.g., physical therapy instructions, video-based preoperative education).

Conclusion

The practice of anesthesiology has changed. The expanding role of the anesthesiologist outside the operating room will redefine the specialty's contribution to high-quality patient care in the healthcare system. Within the context of preoperative evaluation, anesthesiologists must be knowledgeable and adept at assessing patients of highly varying medical complexity, whether in an outpatient preoperative evaluation clinic before the day of the surgical procedure or at the bedside immediately before induction of anesthesia. Anesthesiologists must be familiar with the impact of a broad range of chronic and acute medical conditions on patients' risks for anesthesia and surgery. In addition, this role entails awareness of multiple practice guidelines, regulatory requirements, and approaches for efficient management of outpatient clinics. Despite this evolving and expanding role of anesthesiologists in preoperative care, the primary purpose of preoperative evaluation will never change. It is the clinical foundation for guiding perioperative patient management, and it has the potential to reduce perioperative morbidity and enhance patient outcome.

Acknowledgment

The editors, publisher, and Dr. Duminda Wijeysundera would like to thank Dr. Bobbie-Jean Sweitzer for her contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

Anesthetic Implications of Concurrent Diseases

JESSE KIEFER, MONTY MYTHEN, MICHAEL F. ROIZEN, and
LEE A. FLEISHER

KEY POINTS

- The history and physical examination most accurately predict the risks of anesthesia and the likelihood of required changes in monitoring or therapy.
- For diabetic patients, end-organ dysfunction and the degree of glucose control in the perioperative and periprocedural periods are the critical issues with regard to risk.
- The keys to managing blood glucose levels in diabetic patients perioperatively are to set clear goals and then monitor blood glucose levels frequently enough to adjust therapy to achieve these goals.
- Obesity is associated with multiple comorbid conditions, including diabetes, hyperlipidemia, and cholelithiasis, but the primary concern is derangements of the cardiopulmonary system.
- Obstructive sleep apnea is important to recognize because of the increased sensitivity to and the consequence of the depressing effects of hypnotics and opioids on airway muscle tone and respiration, as well as the difficulty with laryngoscopy and mask ventilation.
- Although no controlled, randomized prospective clinical studies have been performed to evaluate the use of adrenergic receptor blocking drugs in patients undergoing resection of pheochromocytoma, the preoperative use of such drugs is generally recommended.
- For patients with hypertension, the routine administration of all drugs preoperatively is recommended, except angiotensin-converting enzyme inhibitors and angiotensin II antagonists.
- Evaluation of a patient with cardiovascular disease depends on clinical risk factors, the extent of surgery, and exercise tolerance.
- In patients with pulmonary disease, the following should be assessed: dyspnea, coughing and the production of sputum, recent respiratory infection, hemoptysis, wheezing, previous pulmonary complications, smoking history, and physical findings.
- In patients with pulmonary disease, several strategies have been suggested, including cessation of smoking 8 weeks or more preoperatively.
- Risk factors for perioperative renal dysfunction include advanced age, congestive heart failure, previous myocardial revascularization, diabetes, and increased baseline blood creatinine concentration.
- One of the primary objectives for a patient with renal disease is ensuring that the renal dysfunction is not augmented and thereby increasing the chance for renal failure, coma, and death.
- Mild perioperative anemia may be clinically significant only in patients with ischemic heart disease.
- Careful management of long-term drug administration should include questions about the effects and side effects of alternative as well as prescription drugs.

This chapter reviews many conditions requiring special preoperative and preprocedure evaluation, intraoperative or intraprocedure management, or postprocedure care. Patients undergoing surgical procedures move through a continuum of medical care to which a primary care physician, an internist or pediatrician, an anesthesiologist, and a surgeon, gastroenterologist, radiologist, or obstetrician-gynecologist contribute to ensure the best outcome possible. It may also involve comanagement with a hospitalist. No aspect of medical care requires greater cooperation among physicians than does performance of a surgical operation or a complex procedure involving multiple specialists and the perioperative care of a patient. Moreover, nowhere else can counseling make so huge a difference in so many lives. The preoperative evaluation also represents a time when education on tobacco cessation, physical inactivity, brain health, and poor food choices can be discussed. The importance of integrating physicians' expertise is even greater within the context of the increasing life-span of our population. As the number of older adults and very old adults (those >85 years old) grows, so does the need of surgical patients for preoperative consultation to help plan for comorbidity, frailty, and multiple drug regimens, the knowledge of which is crucial to successful patient management. At a time when medical information is encyclopedic, it is difficult, if not impossible, for even the most conscientious anesthesiologist to keep abreast of the medical issues relevant to every aspect of perioperative or periprocedure patient management. This chapter reviews such issues with primary emphasis on the anesthesiologist providing preoperative evaluation and care, rather than transferring these responsibilities to other providers.

As with "healthy" patients, the history and physical examination most accurately predict not only the associated risks but also the likelihood of whether a monitoring technique, change in therapy, or "prehabilitation" will be beneficial or necessary for survival. This chapter emphasizes instances in which specific information should be sought in history taking, physical examination, or laboratory evaluation. Although controlled studies designed to confirm that optimizing a patient's preoperative or preprocedure physical condition would result in a less frequent rate of morbidity have not been performed for most diseases, it is logical to assume that such is the case. That such preventive measures would cost less than treating the morbidity that would otherwise occur is an important consideration in a cost-conscious environment.

Minimally invasive procedures such as cataract extraction, magnetic resonance imaging (MRI), or diagnostic arthroscopy, performed in conjunction with the best current anesthetic practices, may pose no greater risk than daily living and thus may not be considered an opportunity for special evaluation. Nevertheless, the preoperative evaluation may identify conditions that could change perioperative management and that may improve both throughput of surgery and the speed of recovery. Examples include the following: ensuring the administration of long-term medications such as a β-adrenergic blocking drug, aspirin for patients with coronary stents, or a statin (or any combination); administering a histamine type 2 (H_2) antagonist 1 to 2 hours before entry into the operating room; ensuring the availability of equipment to measure blood glucose levels; obtaining a history of the patient's diabetic course and treatment from the primary care physician, as well as from the patient; and performing a fiberoptic laryngoscopic examination or procuring additional skilled attention.

The following conditions are discussed in this chapter:

1. Diseases involving the endocrine system and disorders of nutrition (discussed first because of its increasing importance to care)
2. Diseases involving the cardiovascular system
3. Disorders of the respiratory and immune system
4. Diseases of the central nervous system (CNS), neuromuscular diseases, and mental disorders
5. Diseases involving the kidney, infectious diseases, and disorders of electrolytes
6. Diseases involving the gastrointestinal (GI) tract or the liver
7. Diseases involving hematopoiesis and various forms of cancer
8. Diseases of aging or those that occur more commonly in older adults, as well as chronic and acute medical conditions requiring drug therapy

Role of the Primary Care Physician or Consultant

The roles of the primary care physician or consultant are not to select and suggest anesthetic or surgical methods but rather to optimize the patient's preoperative and preprocedure status regarding conditions that increase the morbidity and mortality associated with surgery and to alert the anesthesia care team about these conditions. Within the context of shared decision making, the primary care physician may also be involved in the decision to proceed with surgery.

Quotations and a box in a Medical Knowledge Self-Assessment Program published by the leading organization representing internists, the American College of Physicians, highlight this role for the consultant[1]:

> *Effective interaction with colleagues in other specialties requires a thorough grounding in the language and science of these other disciplines as well as an awareness of basic guidelines for consultation [Box 32.1]. The consulting internists' role in perioperative care is focused on the elucidation of medical factors that may increase the risks of anesthesia and surgery. Selecting the anesthetic technique for a given patient, procedure, surgeon, and anesthetist is highly individualized and remains the responsibility of the anesthesiologist rather than the internist.*

BOX 32.1 Guidelines for Consultation Practice

- Complete a prompt, thorough, generalist-oriented evaluation.
- Respond specifically to the question or questions posed.
- Indicate clearly the perioperative importance of any observations and recommendations outside the area of initial concern.
- Provide focused, detailed, and precise diagnostic and therapeutic guidance.
- Emphasize verbal communication with the anesthesiologist and surgeon, particularly to resolve complex issues.
- Avoid chart notations that unnecessarily create or exacerbate regulatory or medicolegal risk.
- Use frequent follow-up visits in difficult cases to monitor clinical status and compliance with recommendations.

From American College of Physicians. Medical consultation. *Medical Knowledge Self-Assessment Program IX.* Part C. Book 4. Philadelphia: American College of Physicians; 1992: 939.

Optimizing a patient's preoperative and preprocedure condition and, in settings with a preoperative clinic, counseling a patient about needed future lifestyle changes such as exercise, food choices, and tobacco cessation are cooperative ventures between the anesthesiologist and the internist, pediatrician, surgeon, or family physician. If available, the primary care physician should affirm that the patient is in the very best physical state attainable (for that patient), or the anesthesiologist and primary care physician should do what is necessary to optimize that condition. Although not yet definitively proven, prehabilitation prior to surgery has been advocated by many groups.

Primary care physicians can prepare and treat a patient to provide optimal conditions for daily life. The preoperative clinic should collaborate with the primary care physician to start the process of preparing the patient for the needs of surgery or complex procedures. Although such education is more readily available and of better quality than in previous decades, and although cardiologic organizations have provided considerable data on the importance of this aspect of care,[2-4] the primary care physician's training, knowledge, and ability may not include an in-depth understanding of the perioperative evaluation. Without understanding the physiologic changes that occur perioperatively, appropriate therapy is difficult to prescribe. It is therefore part of the anesthesiologist's job to guide the patient's consultants about the type of information needed from the preoperative and preprocedure consultation.

Diseases Involving the Endocrine System and Disorders of Nutrition

PANCREATIC DISORDERS

Preoperative and Preprocedure Diabetes Mellitus

Diabetes mellitus is a heterogeneous group of disorders that have the common feature of a relative or absolute insulin deficiency. The disease is characterized by a multitude of hormone-induced metabolic abnormalities, diffuse microvascular lesions, and long-term end organ complications. The diagnosis of diabetes is made with a fasting blood glucose level greater than 110 mg/dL (6.1 mmol/L), and impaired glucose tolerance is diagnosed if the fasting glucose level is less than 110 mg/dL (6.1 mmol/L) but greater than 100 mg/dL (5.5 mmol/L). Diabetes can be divided into two very different diseases that share the same long-term end-organ complications. Type 1 diabetes is associated with autoimmune diseases and has a concordance rate of 40% to 50% (i.e., if one of a pair of monozygotic twins had diabetes, the likelihood that the other twin would have diabetes is 40%-50%). In type 1 diabetes, the patient is insulin deficient, principally from autoimmune destruction of the pancreatic β cells, and susceptible to ketoacidosis if insulin is withheld. Type 2 diabetes has a concordance rate approaching 80% (i.e., genetic material is both necessary and sufficient for the development of type 2 diabetes).[4a] How markedly the aging and end-organ effects of these genes are expressed is based on lifestyle choices of food and physical activity. These patients are not susceptible to the development of ketoacidosis in the absence of insulin, and they have peripheral insulin resistance through multiple defects with insulin action and secretion. Patients with non–insulin-dependent (type 2) diabetes account for the majority (>90%) of the diabetic patients in Europe and North America. These individuals tend to be overweight, relatively resistant to ketoacidosis, and susceptible to the development of a hyperglycemic-hyperosmolar nonketotic state. Plasma insulin levels are normal or increased in type 2 diabetes but are relatively low for the level of blood glucose. This hyperinsulinemia by itself is postulated to cause accelerated cardiovascular disease. Gestational diabetes develops in more than 3% of all pregnancies and increases the risk of developing type 2 diabetes by 17% to 63% within 15 years.

Type 1 and type 2 diabetes differ in other ways as well. Contrary to long-standing belief, a patient's age does not allow a firm distinction between type 1 and type 2 diabetes; type 1 diabetes can develop in an older person, and clearly, type 2 diabetes can develop in overweight children. Type 1 diabetes is associated with a 15% prevalence of other autoimmune diseases, including Graves disease, Hashimoto thyroiditis, Addison disease, and myasthenia gravis.

Over the next decade, the prevalence of diabetes is expected to increase by 50%. This growth is primarily the result of the increase in type 2 diabetes caused by excessive weight gain in adults and now also in the pediatric population. Large clinical studies show that long-term, strict control of blood glucose levels and arterial blood pressure, along with regular physical activity, results in a major delay in microvascular complications and perhaps indefinite postponement of type 2 diabetes in patients.[5,6]

The common administered drugs can be classified into eight major groups: acarbose, biguanides (e.g., metformin), dipeptidyl peptidase-4 inhibitors (e.g., sitagliptin, saxagliptin, vildagliptin), glucagon-like peptide-1 receptor agonists (e.g., albiglutide, dulagutide, or exenatide), meglitinide (e.g., repaglinide or nateglinide), sodium-glucose transport protein 2 inhibitors (e.g., canagliflozin or empagliflozin), sulfonylureas (e.g., glibenclamide, glipizide, glimepiride, gliquidone), and thiazolidinediones (e.g., pioglitazone or rosiglitazone).[6a]

Patients with insulin-dependent diabetes tend to be younger, nonobese, and susceptible to the development of ketoacidosis. Plasma insulin levels are low or un-measurable, and therapy requires insulin replacement. Patients with insulin-dependent diabetes experience an increase in their insulin requirements in the post-midnight hours, which may result in early morning hyperglycemia (dawn phenomenon). This accelerated glucose production and impaired glucose use reflect nocturnal surges in secretion of growth hormone (GH). Physiologically normal patients and diabetic patients taking insulin have steady-state levels of insulin in their blood. Absorption of insulin is highly variable and depends on the type and species of insulin, the site of administration, and subcutaneous blood flow. Nevertheless, attainment of a steady state depends on periodic administration of the preparations received by the patient. Thus it seems logical to continue the insulin combination perioperatively that the patient had been receiving after assessing previous blood glucose control.[6b]

The major risk factors for diabetic patients undergoing surgery are the end-organ diseases associated with diabetes: cardiovascular dysfunction, renal insufficiency, joint collagen tissue abnormalities (limitation in neck extension, poor wound healing), inadequate granulocyte production, neuropathies, and infectious complications.[7-15] Thus a major focus of the anesthesiologist should be the preoperative and preprocedure evaluation and treatment of these diseases to ensure optimal preoperative and preprocedure conditions. Poor preoperative glucose control, as measured by the hemoglobin A_{1C} (glycosylated hemoglobin) level, is an independent predictor of worse perioperative outcome.[16-18]

Glucotoxicity

Long-term tight control of blood glucose has been motivated by concern for three potential glucotoxicities, in addition to the results from major randomized outcome studies involving diabetic patients.[5-13]

1. Glucose itself may be toxic because high levels can promote nonenzymatic glycosylation reactions that lead to the formation of abnormal proteins. These proteins may weaken endothelial junctions and decrease elastance, which is responsible for the stiff joint syndrome (and difficult intubation secondary to fixation of the atlanto-occipital joint), as well as decrease wound-healing tensile strength.

2. Glycemia also disrupts autoregulation. Glucose-induced vasodilation prevents target organs from protecting against increases in systemic blood pressure. A glycosylated hemoglobin level of 8.1% is the threshold at which the risk for microalbuminuria increases logarithmically. A person with type 1 diabetes who has microalbuminuria of greater than 29 mg/day has an 80% chance of experiencing renal insufficiency. The threshold for glycemic toxicity differs for various vascular beds. For example, the threshold for retinopathy is a glycosylated hemoglobin value of 8.5% to 9.0% (12.5 mmol/L or 225 mg/dL), and that for cardiovascular disease is an average blood glucose value of 5.4 mmol/L (96 mg/dL). Thus different degrees of hyperglycemia may be required before different vascular beds are damaged. Another view is that perhaps severe hyperglycemia and microalbuminuria are simply concomitant effects of a common underlying cause. For instance, diabetic patients in whom microalbuminuria develops are more resistant to insulin, insulin resistance is associated with microalbuminuria in first-degree relatives of patients with type 2 diabetes, and persons who are normoglycemic but subsequently have clinical diabetes are at risk for atherogenesis before the onset of disease.

Diabetes itself may not be as important to perioperative outcome as are its end-organ effects. Epidemiologic studies segregated the effects of diabetes itself on the organ system from the effects of the complications of diabetes (e.g., cardiac, nervous system, renal, and vascular disease) and the effects of old age and the accelerated aging that diabetes causes. Even in patients requiring intensive care unit (ICU) management, long-standing diabetes does not appear to be as important an issue as the end-organ dysfunction that exists and the degree of glucose control in the perioperative or periprocedure and ICU periods.[6b,8-13]

The World Health Organization's surgical safety checklist bundle suggests control with a target perioperative blood glucose concentration of 6 to 10 mmol/L (acceptable range, 4-12 mmol/L) or 100 to 180 mg/dL.[19] Poor perioperative glycemic control has a significant impact on the risk of postoperative infection across a variety of surgical specialities.[20] Different regimens permit almost any degree of perioperative control of blood glucose levels, but the tighter the control desired, the greater the risk of hypoglycemia. Therefore, debate regarding optimal control during the perioperative period has been extensive. Tight control retards all these glucotoxicities and may have other benefits in retarding the severity of diabetes itself.[5-13,21] Management of intraoperative glucose may be influenced by specific situations, such as the following: the type of operation, pregnancy,[22] expected global CNS insult, the bias of the patient's primary care physician, or the type of diabetes.

Much of the research on perioperative control is derived from studies in the ICU, as opposed to the operating room. The first major trial demonstrating the benefit of tight glucose control was in medical ICU patients in Leuven, Belgium.[23] The most recent trial was from the NICE-SUGAR (Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation) group.[24] In this randomized controlled trial, the investigators examined the associations between moderate and severe hypoglycemia (blood glucose, 41-70 mg/dL [2.3-3.9 mmol/L] and ≤40 mg/dL [2.2 mmol/L], respectively) and death among 6026 critically ill patients in ICUs. Intensive glucose control leads to moderate and severe hypoglycemia, both of which are associated with an increased risk of death. The association exhibits a dose-response relationship and is strongest for death from distributive shock. The optimal perioperative management has been reviewed elsewhere.[25] Guidelines have been developed on the use of insulin infusions in the critical care unit to achieve these goals (Table 32.1).[26]

Diabetes and Accelerated Physiologic Aging

Adverse perioperative outcomes have repeatedly and substantially correlated with the age of the patient,[2,3,27-30] and diabetes does cause physiologic aging. When one translates the results of the Diabetes Control and Complications Trials into age-induced physiologic changes, a patient with type 1 diabetes who has poor control of blood glucose ages approximately 1.75 years physiologically for every chronologic year of the disease and 1.25 years if blood glucose has been controlled tightly.[27-29] A patient with type 2 diabetes ages approximately 1.5 years for every chronologic year of the disease and approximately 1.06 years with tight control of blood glucose and blood pressure.[6,27-29,31] Thus when providing care for a diabetic patient, one must consider the associated risks to be those of a person who is much older physiologically; the physiologic age of a diabetic patient is considerably older than that person's calendar age just by virtue of having the disease.[1]

Obesity and lack of physical exercise seem to be major contributors to the increasing prevalence of type 2 diabetes. As with type 1 diabetes, tight control of blood glucose, increased physical activity, and reduction in weight appear to reduce the accelerated aging associated with type 2 diabetes, and possibly delay the appearance of the disease and aging from it substantially.[27-29,31] Although such a reduction in aging should reduce the perioperative risk for diabetic patients, no controlled trials have confirmed this theory.

The key to managing blood glucose levels perioperatively in diabetic patients is to set clear goals and then monitor blood glucose levels frequently enough to adjust therapy to achieve these goals.[31a]

Other Conditions Associated With Diabetes

Diabetes is associated with microangiopathy (in retinal and renal vessels), peripheral neuropathy, autonomic dysfunction, and infection. Diabetic patients are often treated with angiotensin-converting enzyme (ACE) inhibitors, even in the absence of gross hypertension, in an effort to prevent the effects of disordered autoregulation, including renal failure.[5,6,32]

Preoperatively, assessment and optimization of treatment of the potential and potent end-organ effects of diabetes are at least as important as assessment of the diabetic patient's current overall metabolic status. The preoperative evaluation of diabetic patients is also discussed in Chapter 31.

The presence of autonomic neuropathy likely makes the operative period more hazardous and the postoperative period crucial to survival. Evidence of autonomic neuropathy may be routinely sought before the surgical procedure. Patients with diabetic autonomic neuropathy are at increased risk for gastroparesis (and consequent aspiration

TABLE 32.1 Recommended Glucose Target Ranges for Intensive Care Patients and Related Subgroups

Society, Guideline	Patient Group	Trigger Blood Glucose Value to Start Insulin Infusion (mM [mg/dL])	Target range, (mM [mg/dL])	Rationale
Society of Critical Care Medicine's clinical practice guideline[26]	General recommendation	8.3 (150)	5.6-8.3 (100-150)	
	Cardiac surgical patients		<8.3 (150)	Decreased risk for deep sternal wound infection and death[73,118-121]
	Critically ill trauma patients	8.3 (150)	<10 (180)	
	Patients with traumatic brain injury	8.3 (150)	<10 (180)	
	Neurologic ICU patients Ischemic stroke Intraparenchymal hemorrhage Aneurysmal subarachnoid hemorrhage	8.3 (150)	<10 (180)	
American Diabetes Association guidelines[446]	General recommendation	10 (180)	7.8-10 (140-180)	
	Adaptation		6.1-7.8 (110-140)	Adjust to lower target range in documented low rate of severe hypoglycemia
American Association of Clinical Endocrinologists[447]	General recommendation		7.8-10 (140-180)	
	Surgical patients		Lower range	Only in units showing low rates of hypoglycemia
Surviving Sepsis Campaign[448]	General recommendation	10 (180)	<10 (180)	Based on the NICE-SUGAR study
Clinical Practical Guideline from the American College of Physicians[449]	General recommendation		7.8-11.1 (140-200)	If insulin infusion is applied; however, guideline does not recommend intensive insulin therapy
Spanish Society of Intensive Care Medicine and Coronary Units[450]	General recommendation		<8.3 (150)	
French Society of Anesthesia and Intensive Care[451]	General recommendation		10 (180)	
	Surgical patients		<6.1 (110)	
	Cardiac patients		<6.1 (110)	
Society of Thoracic Surgeons[452]	Cardiac surgical patients		<10 (180) except <8.3 (150) for those with devices in place

Guidelines for the use of an insulin infusion for the management of hyperglycemia in critically ill patients. *Crit Care Med.* 2012;40:3251–3276.

of gastric contents) and for perioperative cardiorespiratory arrest. Diabetic patients who exhibit signs of autonomic neuropathy, such as early satiety, lack of sweating, lack of pulse rate change with inspiration or orthostatic maneuvers, and impotence, have a very frequent incidence of painless myocardial ischemia.[15,33] Administration of metoclopramide, 10 mg preoperatively to facilitate gastric emptying of solids, may be helpful (Fig. 32.1). Interference with respiration or sinus automaticity by pneumonia or by anesthetic agents, pain medications, or sedative drugs is likely the precipitating cause in most cases of sudden cardiorespiratory arrest. Measuring the degree of sinus arrhythmia or beat-to-beat variability provides a simple, accurate test for significant autonomic neuropathy. The difference between the maximum and minimum heart rate on deep inspiration is normally 15 beats/min, but it is 5 beats/min or less in all patients who subsequently sustain cardiorespiratory arrest.[15,33]

Other characteristics of patients with autonomic neuropathy include postural hypotension with a decrease in arterial blood pressure of more than 30 mm Hg, resting tachycardia, nocturnal diarrhea, and dense peripheral neuropathy. Diabetic patients with significant autonomic neuropathy may have impaired respiratory responses to

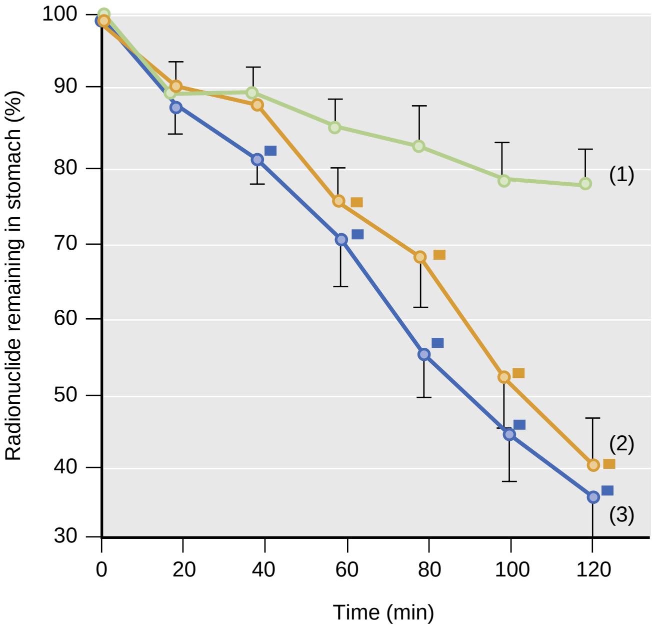

Fig. 32.1 Gastric emptying time (mean ± standard deviation) of a solid test meal in three groups of patients: diabetic patients *(line 1)*, diabetic patients given metoclopramide (10 mg intravenously) 1.5 hours before the test meal *(line 2)*, and nondiabetic patients *(line 3)*. (From Wright RA, Clemente R, Wathen R. Diabetic gastroparesis: an abnormality of gastric emptying of solids. *Am J Med Sci.* 1985;289:240–242.)

hypoxia and are particularly sensitive to the action of drugs that have depressant effects. These patients may warrant continuous cardiac and respiratory monitoring for 24 to 72 hours postoperatively, although this has not been tested in a rigorous, controlled trial.[15] In the absence of autonomic neuropathy, outpatient surgery is preferred for a diabetic patient if possible (see Table 32.1).[31a]

Emergency Surgery

Many diabetic patients requiring emergency surgery for trauma or infection have significant metabolic decompensation, including ketoacidosis. Frequently, little time is available to stabilize the patient, but even a few hours may be sufficient for correction of any fluid and electrolyte disturbances that are potentially life-threatening. It is futile to delay surgery in an attempt to eliminate ketoacidosis completely if the underlying surgical condition will lead to further metabolic deterioration. The likelihood of intraoperative cardiac arrhythmias and hypotension resulting from ketoacidosis will be reduced if intravascular volume depletion and hypokalemia are at least partially treated. During the initial resuscitation phase of ketoacidosis bicarbonate should initially be avoided with crystalloid fluids, potassium repletion, and intravenous insulin therapy favored.[33a]

Insulin therapy is initiated with a 10-unit intravenous bolus of regular insulin, followed by continuous insulin infusion. The rate of infusion is determined most easily by dividing the last serum glucose value by 150 (or 100 if the patient is receiving steroids, has an infection, or is considerably overweight [body mass index ≥35]). The actual amount of insulin administered is less important than is regular monitoring of glucose, potassium, and arterial pH. The maximum rate of glucose decline is fairly constant, averaging 75 to 100 mg/dL/h, regardless of the dose of insulin because the number of insulin binding sites is limited.[34] During the first 1 to 2 hours of fluid resuscitation, the glucose level may decrease more precipitously. When serum glucose reaches 250 mg/dL, the intravenous fluid should include 5% dextrose.

The volume of intravenously administered fluid required varies with the overall deficit; it ranges from 3 to 5 L and may be as large as 10 L. Despite losses of water in excess of losses of solute, sodium levels are generally normal or reduced. Factitious hyponatremia caused by hyperglycemia or hypertriglyceridemia may result in this seeming contradiction. The plasma sodium concentration decreases by approximately 1.6 mEq/L for every 100 mg/dL increase in plasma glucose greater than normal. Initially, balanced crystalloid solution is infused at a rate of 250 to 1000 mL/h, depending on the degree of intravascular volume depletion and cardiac status. Some measure of left ventricular volume should be monitored in diabetic patients who have a history of myocardial dysfunction. Approximately one third of the estimated fluid deficit is corrected during the first 6 to 8 hours and the remaining two thirds over the next 24 hours.[34a]

The degree of acidosis is determined by analysis of arterial blood gases and detection of an increased anion gap (see also Chapter 48). Acidosis with an increased anion gap (≥16 mEq/L) in an acutely ill diabetic patient may be caused by ketones in ketoacidosis, lactic acid in lactic acidosis, increased organic acids from renal insufficiency, or all three disorders. In ketoacidosis, plasma levels of acetoacetate, β-hydroxybutyrate, and acetone are increased. Plasma and urinary ketones can be measured semiquantitatively with Ketostix and Acetest tablets. The role of bicarbonate therapy in diabetic ketoacidosis is controversial, but could be considered in severe acidemia and hemodynamic instability as myocardial function and respiration are known to be depressed at a blood pH lower than 7.00 to 7.10.[34b] This careful consideration is because rapid correction of acidosis with bicarbonate therapy may result in alterations in CNS function and structure. These alterations may be caused by (1) paradoxical development of cerebrospinal fluid and CNS acidosis from rapid conversion of bicarbonate to carbon dioxide and diffusion of the acid across the blood-brain barrier, (2) altered CNS oxygenation with decreased cerebral blood flow, and (3) the development of unfavorable osmotic gradients. After treatment with fluids and insulin, β-hydroxybutyrate levels decrease rapidly, whereas acetoacetate levels may remain stable or even increase before declining. Plasma acetone levels remain elevated for 24 to 42 hours, long after blood glucose, β-hydroxybutyrate, and acetoacetate levels have returned to normal; the result is continuing ketonuria.[34] Persistent ketosis with a serum bicarbonate level less than 20 mEq/L in the presence of a normal glucose concentration is an indication of the continued need for intracellular glucose and insulin for reversal of lipolysis.

The most important electrolyte disturbance in diabetic ketoacidosis is depletion of total-body potassium. Deficits range from 3 to 10 mEq/kg body weight. Serum potassium levels decline rapidly and reach a nadir within 2 to 4 hours after the start of intravenous insulin administration. Aggressive replacement therapy is required. The potassium administered moves into the intracellular space with insulin as the acidosis is corrected. Potassium is also excreted in urine because of the increased delivery of sodium to the distal renal tubules that accompanies volume expansion. Phosphorus deficiency in ketoacidosis as a result of tissue catabolism, impaired cellular uptake, and increased urinary losses may give rise to significant muscular weakness and organ dysfunction. The average phosphorus deficit is approximately 1 mmol/kg body weight; no clear guidance for replacement exists, but replacement is appropriate in patients with cardiac dysfunction, anemia, respiratory depression, or if the plasma phosphate concentration is less than 1.0 mg/dL.[34]

Anticipated Newer Treatments of Diabetes

At least three major changes in the care of diabetic patients have made it to the clinical trial stage:

- Implanted (like a pacemaker) glucose analyzer with electronic transmission to a surface (watch) monitor
- New islet transplantation medication that makes islet cell transplants much more successful and rejection medication less hazardous
- Medications such as INGAP (islet neogenesis–associated protein) peptide, which may cause regrowth of normally functioning islet cells (without the need for transplantation)

Some of these treatments may radically change the therapies used in the perioperative period. If regrowth of islet cells becomes common, type 1 diabetes could all but disappear; if implanted minute-to-minute glucose reading is possible, tight control may be much easier and more expected.

Insulinoma and Other Causes of Hypoglycemia

Hypoglycemia in persons not treated for diabetes is rare. Hypoglycemia in nondiabetic patients can be caused by such diverse entities as pancreatic islet cell adenoma or carcinoma, large hepatoma, large sarcoma, alcohol ingestion, use of β-adrenergic receptor blocking drugs, haloperidol therapy, hypopituitarism, adrenal insufficiency, altered physiology after gastric or gastric bypass surgery, hereditary fructose intolerance, ingestion of antidiabetic drugs, galactosemia, or autoimmune hypoglycemia.[35] The last four entities cause postprandial reactive hypoglycemia. Because restriction of oral intake prevents severe hypoglycemia, the practice of keeping the patient NPO (nothing by mouth) and infusing small amounts of a solution containing 5% dextrose greatly lessens the possibility of perioperative postprandial reactive hypoglycemia. The other causes of hypoglycemia can cause serious problems during the perioperative period.[35]

Symptoms of hypoglycemia fall into one of two groups: adrenergic excess (tachycardia, palpitations, tremulousness, or diaphoresis) or neuroglycopenia (headache, confusion, mental sluggishness, seizures, or coma). All these symptoms may be masked by anesthesia, so blood glucose levels should be determined frequently in at-risk patients to ensure that hypoglycemia is not present. Because manipulation of an insulinoma can result in massive insulin release, this tumor should probably be operated on only at centers equipped with a mechanical pancreas. Perioperative use of the somatostatin analogue octreotide, which suppresses insulin release from such tumors, makes the perioperative period safer in anecdotal experience.

DISORDERS OF NUTRITION, INCLUDING OBESITY

Hyperlipoproteinemia, Hyperlipidemia, and Hypolipidemia

Hyperlipidemia may result from obesity, estrogen or corticoid therapy, uremia, diabetes, hypothyroidism, acromegaly, alcohol ingestion, liver disease, inborn errors of metabolism, or pregnancy. Hyperlipidemia may cause premature coronary, peripheral vascular disease, or pancreatitis.

Coronary events can be decreased by treating individuals with even normal levels of low-density lipoprotein (LDL) cholesterol with statins (3-hydroxy-3-methylglutaryl–coenzyme A [HMG-CoA] reductase inhibitors)—through an increase in high-density lipoprotein (HDL) and a decrease in LDL cholesterol levels. This approach has markedly decreased the rate of myocardial reinfarction in high-risk patients.[36-38] Secondary prevention efforts were successful when these high-risk patients stopped smoking, reduced their arterial blood pressure, controlled stress, increased physical activity, and used aspirin, folate, β-blocking drugs, angiotensin inhibitors, diet, and other drugs to reduce their levels of LDL and increase their levels of HDL.

Although controlling the diet remains a major treatment modality for all types of hyperlipidemia, the drugs fenofibrate and gemfibrozil, which are used to treat hypertriglyceridemia, can cause myopathy, especially in patients with hepatic or renal disease; clofibrate is also associated with an increased incidence of gallstones. Cholestyramine binds bile acids, as well as oral anticoagulants, digitalis drugs, and thyroid hormones. Nicotinic acid causes peripheral vasodilation and should probably not be continued through the morning of the surgical procedure. Probucol (Lorelco) decreases the synthesis of apoprotein A-1; its use is associated on rare occasion with fetid perspiration or prolongation of the QT interval, or both, and sudden death in animals.

The West of Scotland Coronary Prevention Study and its congeners produced convincing evidence that drugs in the statin class prevent the morbidity and mortality related to arterial aging and vascular disease, as well as their consequences, such as coronary artery disease (CAD), stroke, and peripheral vascular insufficiency.[37] Thus, the statins—lovastatin (Mevacor), pravastatin (Pravachol), simvastatin, fluvastatin, atorvastatin (Lipitor), and rosuvastatin (Crestor)—are mainstays of therapy, limited by patient tolerance most commonly secondary to musculoskeletal complaints.[38a]

However, the report of Downs and coworkers from the Air Force/Texas Coronary Atherosclerosis Prevention Study went further.[37] This report showed a 37% reduction in the risk for first acute major coronary events in patients who had no risk factors and normal (average) LDL cholesterol levels. In this study lovastatin did not alter mortality rates, but that had been true for many early short-term trials with the statins. Although much of the effect of the statins has been attributed to their lipid-lowering effects, statins also influence endothelial function, inflammatory responses, plaque stability, and thrombogenicity. In 2013, the American College of Cardiology (ACC) and the American Heart Association (AHA) released a new clinical practice guideline for the treatment of blood cholesterol in people at high risk for cardiovascular diseases.[39] They now advocate statin therapy for the following:

- Patients who have cardiovascular disease (coronary syndromes, previous myocardial infarction [MI], stable or unstable angina, previous stroke or transient ischemic attack, or peripheral artery disease)
- Patients with an LDL cholesterol level of 190 mg/dL or higher
- Patients with diabetes (type 1 or 2) who are between 40 and 75 years old
- Patients with an estimated 10-year risk of cardiovascular disease greater than 7.5% (the report provided formulas for calculating 10-year risk)

The 2014 National Lipid Association Recommendations for Patient-Centered Management of Dyslipidemia further emphasize the use of statins as a first-line therapy for dyslipidemia, but emphasize the inclusion of non-high density lipoprotein in addition to LDL as markers for risk. They further advocated for management of other atherosclerotic cardiovascular disease risk factors including high blood pressure, tobacco use, and diabetes mellitus.[39a]

Statins are drugs that block HMG-CoA reductase, the rate-limiting enzyme of cholesterol synthesis. Their use is occasionally accompanied by liver dysfunction, CNS dysfunction, and severe depression not related to the high cost of each drug and its congeners. Based on the available evidence, statin therapy should be continued in patients already taking these drugs.[40] Other drugs that reduce LDL and increase HDL cholesterol and decrease triglycerides are docosahexaenoic acid (an ω-3 fatty acid) and niacin. Statins also provide the substantial benefit of reversing inflammation in arteries, as evidenced by their ability to decrease highly specific C-reactive protein and pull cholesterol from plaque.[41]

Hypolipidemic conditions are rare diseases often associated with neuropathy, anemia, and renal failure. Although anesthetic experience with hypolipidemic conditions has been limited, some specific recommendations can be made: continuation of caloric intake and intravenous administration of protein hydrolysates and glucose should be continued throughout the perioperative period.

Obesity

Obesity is a risk factor for perioperative morbidity. In the study of Medicare claims in which obese patients were matched to non-obese patients undergoing surgery, the obese patients displayed increased odds of wound infection, renal dysfunction, urinary tract infection, hypotension, respiratory events, 30-day readmission, and a 12% longer length of stay.[41a] Although many conditions associated with obesity (diabetes, hyperlipidemia, cholelithiasis, gastroesophageal reflux disease, cirrhosis, degenerative joint and disk disease, venous stasis with thrombotic or embolic disease, sleep disorders, and emotional and altered body image disorders) contribute to chronic morbidity in these patients, the main concerns for the anesthesiologist have been the same since the 1970s—derangements of the cardiopulmonary system.

Morbid obesity with minimal or no coexisting pulmonary conditions (e.g., no obesity-hypoventilation syndrome or chronic obstructive pulmonary disease [COPD]) is referred to here as "simple" obesity. In simple obesity, the pathophysiology of mild alterations in daytime gas exchange and pulmonary function may also result from compression and restriction of the chest wall and diaphragm by excess adipose tissue.[42] Typically, in obese patients, the expiratory reserve volume and functional residual capacity are most affected and are reduced to 60% and 80% of normal, respectively. Care must be taken with medication choice and dosing, as simple obese patients may be more sensitive to sedative and narcotic agents leading to hypoventilation.[42a]

Other Eating Disorders: Anorexia Nervosa, Bulimia, and Starvation

Many endocrine and metabolic abnormalities occur in patients with anorexia nervosa, a condition characterized by starvation to the point of 40% loss of normal weight, hyperactivity, and a psychiatrically distorted body image. Many anorectic patients exhibit impulsive behavior, including suicide attempts, and intravenous drug use is much more common than in the general population. Acidosis, hypokalemia, hypocalcemia, hypomagnesemia, hypothermia, diabetes insipidus, and severe endocrine abnormalities mimicking panhypopituitarism may need attention before patients undergo anesthesia. Similar problems occur in bulimia (bulimorexia), a condition that may affect as many as 50% of female college students and is even unintentionally present in many older adults. As in severe protein deficiency, anorexia nervosa and bulimia may be accompanied by the following: alterations on the electrocardiogram (ECG), including a prolonged QT interval, atrioventricular (AV) block, and other arrhythmias; sensitivity to epinephrine; and cardiomyopathy.[43] Total depletion of body potassium makes the addition of potassium to glucose solutions useful; although, fluid administration can precipitate pulmonary edema in these patients and should be monitored judiciously. Esophagitis, pancreatitis, and aspiration pneumonia are more frequent in these patients, as is delayed gastric emptying. One review reported that in patients with severe anorexia, a body mass index less than 13 kg/m^2, marked hypoglycemia or leukocytopenia lower than 3.0×10^9/L, or both, potentially fatal complications frequently occur.[44] Intraoperatively, glucose or catecholamine administration may lead to disturbance of electrolytes or fatal arrhythmia. Intensive care and early nutritional support as soon as possible postoperatively are important to prevent surgical site infection with close monitoring for refeeding syndrome.

HYPERALIMENTATION (TOTAL PARENTERAL OR ENTERAL NUTRITION)

Hyperalimentation (i.e., total parenteral nutrition [TPN]) consists of concentrating hypertonic glucose calories in the normal daily fluid requirements. The solutions contain protein hydrolysates, soybean emulsions (i.e., Intralipid), or synthetic amino acids (or any combination of these ingredients). The major benefits of TPN or enteral nutrition have been fewer complications postoperatively and shorter hospital stays for patients scheduled to have no oral feeding for 7 days or who were malnourished preoperatively.[45,46] Starker and colleagues found that the response to TPN, as monitored by serum albumin levels, predicted the postoperative outcome.[47] The group of patients demonstrating

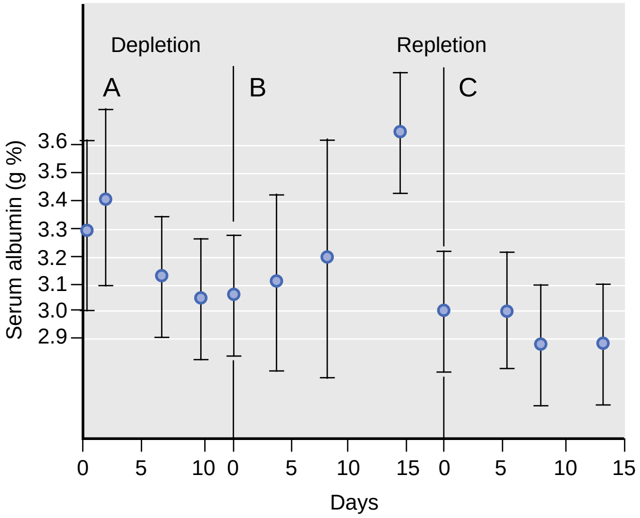

Fig. 32.2 The response to hyperalimentation (*A*, repletion), as measured by variation in serum albumin levels, predicted the outcome of surgery. Patients who responded *(B)* to nutritional support with increased albumin levels had a significantly better outcome than did those whose albumin level did not increase *(C)*. See the text for a more complete explanation. (Modified from Starker PM, Group FE, Askanazi J, et al. Serum albumin levels as an index of nutritional support. *Surgery*. 1982;91:194–199.)

an increase in serum albumin concentrations from TPN had diuresis, weight loss, and fewer complications (1 of 15 patients) than did the group that gained weight and had a decrease in serum albumin (8 of 16 patients had 15 complications; Fig. 32.2). The Veterans Administration (former name for Veterans Affairs [VA used for both]) studies also found that the serum albumin level was one of the most powerful predictors of perioperative outcome.[45]

The major complications of TPN are infection, metabolic abnormalities, and longer duration of ICU stay.[47a] The central lines used for TPN require an absolutely aseptic technique and should not be used as an intravenous access or as a route for drug administration during anesthesia and surgery. Major metabolic complications of TPN relate to electrolyte deficiencies, and the development of hyperosmolar states. Complications of hypertonic dextrose can develop if the patient has insufficient insulin (diabetes mellitus) to metabolize the sugar or if insulin resistance occurs (e.g., because of uremia, burns, or sepsis).

A gradual decrease in the infusion rate of TPN prevents the hypoglycemia that can occur on abrupt discontinuance. Thus the infusion rate of TPN should be decreased the night before anesthesia and surgery, or should be continued throughout the operation at its current rate. The main reason for slowing or discontinuing TPN before anesthesia is to avoid intraoperative hyperosmolarity secondary to accidental rapid infusion of the solution or hypoglycemia if the infusion is discontinued because of high levels of endogenous insulin and lower levels of glucose present in the usual crystalloid solutions.[45] Hypophosphatemia is a particularly serious complication that results from the administration of phosphate-free or phosphate-depleted solutions for hyperalimentation. The low serum phosphate level causes a shift of the oxygen dissociation curve to the left. The resulting low 2,3-diphosphoglycerate and adenosine triphosphatase levels mean that cardiac output must increase for oxygen delivery to remain the same. Hypophosphatemia of less than 1.0 mg/dL of blood may cause hemolytic anemia, cardiac failure, tachypnea, neurologic symptoms, seizures, and death. In addition, long-term TPN is associated with deficiencies in trace metals such as copper (refractory anemia), zinc (impaired wound healing), and magnesium.

ADRENOCORTICAL MALFUNCTION

Three major classes of hormones—androgens, glucocorticoids, and mineralocorticoids—are secreted by the adrenal cortex. For each class, an excess or a deficiency of hormone produces a characteristic clinical syndrome. The widespread use of steroids can also make the adrenal cortex unable to respond normally to the demands placed on it by surgical trauma and subsequent healing. The increase in computed tomography (CT) abdominal imaging procedures has meant that many adrenal masses have unfortunately been discovered incidentally. These adrenal "incidentalomas," as they are termed because they were initially thought a nuisance discovered by body scans, have proved more serious. As many as 30% are hormonally active; in one review of 2000 such masses, 82% were not hormonally active, 5.3% proved to be cortisone-secreting adenomas, 5.1% were pheochromocytomas, 4.7% were adrenal carcinomas, 2.5% were unsuspected metastatic disease, and 1% were aldosterone-secreting adenomas. "Incidentalomas" may therefore require serious pursuit; however, well accepted and utilized guidelines are absent, but caution should be taken during anesthesia.

Controlled comparisons of the perioperative management of patients who have disorders of adrenal function are lacking, although steroids are used more and more commonly, with the results of some controlled trials available for specific uses. However, a review of the possible pathophysiologic changes in the adrenal cortex and techniques for their management should enable physicians to improve the perioperative care of patients with adrenal abnormalities.

Physiologic Properties of Adrenocortical Hormones

Androgens. Androstenedione and dehydroepiandrosterone, weak androgens arising from the adrenal cortex, constitute major sources of androgen in women (and have gained prominence for their abuse among athletes). Excess secretion of androgen causes masculinization, pseudopuberty, or female pseudohermaphroditism. With some tumors, androgen is converted to an estrogenic substance, in which case feminization results. No special anesthetic evaluation is needed for such patients. Some congenital enzyme defects that cause androgen abnormalities also result in glucocorticoid and mineralocorticoid abnormalities that should be evaluated preoperatively. Most of these patients are treated with exogenous glucocorticoids and mineralocorticoids and may require supplementation of these hormones perioperatively.

Glucocorticoids. The principal glucocorticoid, cortisol, is an essential regulator of carbohydrate, protein, lipid, and nucleic acid metabolism. Cortisol exerts its biologic effects through a sequence of steps initiated by the binding of hormone to stereospecific intracellular cytoplasmic receptors.

This bound complex stimulates nuclear transcription of specific mRNA molecules. These molecules are then translated to give rise to proteins that mediate the ultimate effects of hormones.

Most cortisol is bound to corticosterone-binding globulin (CBG, transcortin). The relatively small amounts of unbound cortisol enter cells to induce actions or to be metabolized. Conditions that induce changes in the amount of CBG include liver disease and nephrotic syndrome, both of which result in decreased circulating levels of CBG, and estrogen administration and pregnancy, which result in increased CBG production. Total serum cortisol levels may become elevated or depressed under conditions that alter the amount of bound cortisol, and yet the unbound, active form of cortisol is present in normal amounts. The most accurate measure of cortisol activity is the level of urinary cortisol (i.e., the amount of unbound, active cortisol filtered by the kidney).

The serum half-life of cortisol is 80 to 110 minutes. However, because cortisol acts through intracellular receptors, pharmacokinetic data based on serum levels are not good indicators of cortisol activity. After a single dose of glucocorticoid, serum glucose is elevated for 12 to 24 hours; improvement in pulmonary function in patients with bronchial asthma can still be measured 24 hours after glucocorticoid administration. Treatment schedules for glucocorticoid replacement are therefore based not on the measured serum half-life but on the well-documented prolonged end-organ effect of these steroids. Hospitalized patients requiring long-term glucocorticoid replacement therapy are usually treated twice daily, with a slightly higher dose given in the morning than in the evening to simulate the normal diurnal variation in cortisol levels. For patients who require parenteral "steroid coverage" during and after surgery (see later paragraphs), administration of glucocorticoid every 6 to 12 hours is appropriate pending the type of surgery and expected stress response.[47b] The relative potencies of glucocorticoids are listed in Table 32.2. Cortisol is inactivated primarily in the liver and is excreted as 17-hydroxycorticosteroid. Cortisol is also filtered and excreted unchanged into urine.

The synthetic glucocorticoids vary in their binding specificity in a dose-related manner. When given in supraphysiologic doses (>30 mg/day), cortisol and cortisone bind to mineralocorticoid receptor sites, and cause salt and water retention and loss of potassium and hydrogen ions. When these steroids are administered in maintenance doses of 30 mg/day or less, patients require a specific mineralocorticoid for electrolyte and volume homeostasis. Many other steroids do not bind to mineralocorticoid receptors, even at high doses, and have no mineralocorticoid effect (see Table 32.2).[47b]

Secretion of glucocorticoids is regulated by pituitary adrenocorticotropic hormone (ACTH). ACTH is synthesized from a precursor molecule (pro-opiomelanocortin) that is metabolized to form an endorphin (β-lipotropin) and ACTH. Episodic secretion of ACTH has a diurnal rhythm that is normally greatest during the early morning hours in men and later in women and is regulated at least in part by light-dark cycles. Its secretion is stimulated by release of corticotropin-releasing factor (CRF) from the hypothalamus. (An abnormality in the diurnal rhythm of corticoid secretion has been implicated as a cause of so-called jet lag.) Cortisol and other glucocorticoids exert negative feedback at both the pituitary and hypothalamic levels to inhibit the secretion of ACTH and CRF. If the CRF- or ACTH-producing cells are destroyed, the adrenal gland takes more than 30 days to atrophy to the point at which short-term administration of exogenous ACTH will cause almost no adrenal responsiveness.[48]

TABLE 32.2 Relative Potencies and Equivalent Doses for Commonly Used Glucocorticoids

Steroids	Relative Glucocorticoid Potency	Equivalent Glucocorticoid Dose (mg)
SHORT ACTING		
Cortisol (hydrocortisone)	1.0	20.0
Cortisone	0.8	25.0
Prednisone	4.0	5.0
Prednisolone	4.0	5.0
Methylprednisolone	5.0	4.0
INTERMEDIATE ACTING		
Triamcinolone	5.0	4.0
LONG ACTING		
Betamethasone	25.0	0.60
Dexamethasone	30.0	0.75

Data from Axelrod L. Glucocorticoid therapy. *Medicine (Baltimore).* 1976;55:39–65.

Mineralocorticoids. Aldosterone, the major mineralocorticoid secreted in humans, comes from the zona glomerulosa of the adrenal cortex and causes reabsorption of sodium and secretion of potassium and hydrogen ions, thereby contributing to electrolyte and volume homeostasis. This action is most prominent in the distal renal tubule but also occurs in the salivary and sweat glands. The major regulator of aldosterone secretion is the renin-angiotensin system. Juxtaglomerular cells in the cuff of renal arterioles are sensitive to decreased renal perfusion pressure or volume and, consequently, secrete renin. Renin transforms the precursor angiotensinogen (from the liver) into angiotensin I, which is further converted by a converting enzyme, primarily in the lung, to angiotensin II. Angiotensin II binds to specific receptors to increase mineralocorticoid secretion, which is also stimulated by an increased potassium concentration and, to a lesser degree, by ACTH.

Adrenocortical Hormone Excess

Glucocorticoid Excess. Glucocorticoid excess (Cushing syndrome) resulting from either endogenous oversecretion or long-term treatment with glucocorticoids at higher than physiologic doses produces a moon-faced plethoric individual with a centripetal distribution of fat (truncal obesity and skinny extremities), thin skin, easy bruising, and striae. Skeletal muscle wasting is common, but the heart and diaphragm are usually spared. A test for this syndrome is to ask the patient to get up from a chair without using the hands with the inability to do so indicating proximal

TABLE 32.3 Clinical Features of Hyperadrenalism (Cushing Syndrome) and Hypoadrenalism

Cushing Syndrome	Hypoadrenalism
Central obesity	Weight loss
Proximal muscle weakness	Weakness, fatigue, lethargy
Osteopenia at a young age	Muscle, joint, and back pain
Hypertension	Postural hypotension and dizziness
Headache	Headache
Psychiatric disorders	Anorexia, nausea, abdominal pain, constipation, diarrhea
Purple striae	
Spontaneous ecchymoses	
Plethoric facies	
Hyperpigmentation	Hyperpigmentation
Hirsutism	
Acne	
Hypokalemic alkalosis	Hyperkalemia, hyponatremia
Glucose intolerance	Occasional hypoglycemia
Kidney stones	Hypercalcemia
Polyuria	Prerenal azotemia
Menstrual disorders	
Increased leukocyte count	

muscle weakness consistent with Cushing syndrome. These patients often have osteopenia as a result of decreased formation of bone matrix and impaired absorption of calcium. Fluid retention and hypertension (because of increases in renin substrate and vascular reactivity caused by glucocorticoid activity) are common. Such patients may also have hyperglycemia and even diabetes mellitus from inhibition of peripheral use of glucose, as well as anti-insulin action and concomitant stimulation of gluconeogenesis (Table 32.3).

The most common cause of Cushing syndrome is the administration of glucocorticoids for such conditions as arthritis, asthma, and allergies. In these conditions, the adrenal glands atrophy and cannot respond to stressful situations (e.g., the perioperative period) by secreting more steroid; therefore, additional glucocorticoids may be required perioperatively (see the later section "Patients Taking Steroids for Other Reasons"). Spontaneous Cushing syndrome may be caused by pituitary production of ACTH (65% to 75% of all spontaneous cases), which is usually associated with pituitary microadenoma, or by nonendocrine ectopic ACTH production (principally by tumors of the lung, pancreas, or thymus).[49] Ten percent to 20% of cases of spontaneous Cushing syndrome are caused by an ACTH-independent process, either an adrenal adenoma or carcinoma.[49]

Special preoperative and preprocedure considerations for patients with Cushing syndrome include regulating blood glucose control, managing hypertension, and ensuring intravascular volume and electrolyte concentrations are normal. Ectopic ACTH production may cause marked hypokalemic alkalosis. Treatment with the aldosterone antagonist spironolactone stops the potassium loss and helps mobilize excess fluid. Because of the incidence of severe osteopenia and the risk of fractures, meticulous attention must be paid to positioning of the patient. In addition, glucocorticoids are lympholytic and immunosuppressive, thus increasing the patient's susceptibility to infection. The tensile strength of healing wounds decreases in the presence of glucocorticoids, an effect that is at least partially reversed by the topical administration of vitamin A.

Ten percent to 15% of patients with Cushing syndrome exhibit adrenal overproduction of glucocorticoids from an adrenal adenoma or carcinoma. If either unilateral or bilateral adrenal resection is planned, the physician should begin administering glucocorticoids at the start of resection of the tumor. Despite the absence of definitive studies, 100 mg of hydrocortisone every 24 hours intravenously is reasonable. This amount can be reduced over a period of 3 to 6 days until a maintenance dose is reached. Beginning on day 3, the surgeons may also give a mineralocorticoid, 9α-fluorocortisol (0.05-0.1 mg/day). In certain patients, both steroids may require several adjustments. This therapy continues if the patient has undergone bilateral resection. For a patient who has undergone unilateral adrenal resection, therapy is individualized according to the status of the remaining adrenal gland. The incidence of pneumothorax in an open adrenal resection approach can be as high as 20%; the diagnosis of pneumothorax is sought and treatment is initiated before the wound is closed. The use of the laparoscopic technique has markedly decreased this complication.

Bilateral adrenalectomy (now performed laparoscopically) in patients with Cushing syndrome is associated with a perioperative morbidity rate up to 20% and a perioperative mortality rate up to 3%. This procedure often results in permanent mineralocorticoid and glucocorticoid deficiency.[49a] Ten percent of patients with Cushing syndrome who undergo adrenalectomy have an undiagnosed pituitary tumor. After cortisol concentrations are decreased by adrenalectomy, the pituitary tumor will likely enlarge. These pituitary tumors are potentially invasive and may produce large amounts of ACTH and melanocyte-stimulating hormone, thereby increasing pigmentation.

Approximately 85% of adrenal tumors are discovered incidentally during screening CT scans. Nonfunctioning adrenal adenomas are found in patients on autopsy, ranging from 1% to 32% in different series. Functioning adenomas are generally treated surgically; often, the contralateral gland resumes functioning after several months. Frequently, however, the effects of carcinomas are not cured surgically. In such cases, administration of inhibitors of steroid synthesis, such as metyrapone or mitotane (*o*,*p*′-DDD[2,2-bis(2-chlorophenyl4-chlorophenyl)-1,1-dichloroethane]), may ameliorate some symptoms, as these drugs and specific aldosterone antagonists may aid in reducing symptoms of ectopic ACTH secretion if the primary tumor is unresectable. Patients given these adrenal suppressants are also prescribed long-term glucocorticoid replacement therapy with the goal of therapy being complete adrenal suppression. Therefore, these patients should be considered to have suppressed adrenal function, and glucocorticoid replacement should be increased perioperatively.

Mineralocorticoid Excess. Excess mineralocorticoid activity (common with glucocorticoid excess because most glucocorticoids have some mineralocorticoid properties) leads to potassium depletion, sodium retention, muscle weakness, hypertension, tetany, polyuria, inability to concentrate urine, and hypokalemic alkalosis. These symptoms constitute primary hyperaldosteronism, or Conn syndrome (a cause of low-renin hypertension because renin secretion is inhibited by the effects of the high levels of aldosterone).

Primary hyperaldosteronism is present in 0.5% to 1% of hypertensive patients who have no other known cause of hypertension. Primary hyperaldosteronism most often results from unilateral adenoma, although 25% to 40% of patients have been found to have bilateral adrenal hyperplasia. Intravascular fluid volume, electrolyte concentrations, and renal function should be restored to within normal limits preoperatively by administering the aldosterone antagonist spironolactone. The effects of spironolactone are slow in onset and increase for 1 to 2 weeks. Frequently, a period of at least 24 hours is required to restore potassium equilibrium as the deficit can be up to 400 mEq; however, normal serum potassium level does not necessarily imply correction of a total-body deficit of potassium. In addition, patients with Conn syndrome have a high incidence of hypertension and ischemic heart disease; hemodynamic monitoring should be tailored to the individual patient.

A retrospective anecdotal study indicated that intraoperative hemodynamic status was more stable when arterial blood pressure and electrolytes were controlled preoperatively with spironolactone than when other antihypertensive agents were used. However, the efficacy of optimizing the perioperative status of patients who have disorders of glucocorticoid or mineralocorticoid secretion has not been clearly defined. Therefore, we have assumed that gradual restoration of physiologic norms is good medicine and expect that it would decrease perioperative morbidity and mortality.

Adrenocortical Hormone Deficiency

Glucocorticoid Deficiency. Withdrawal of steroids or suppression of synthesis by steroid therapy is the leading cause of underproduction of corticosteroids (its management is discussed in the later section "Patients Taking Steroids for Other Reasons"). Other causes of adrenocortical insufficiency include the following: defects in ACTH secretion and destruction of the adrenal gland by autoimmune disease, tuberculosis, hemorrhage (e.g., Sheehan syndrome), or cancer; some forms of congenital adrenal hyperplasia (see previous discussion); and administration of cytotoxic drugs.

Primary adrenal insufficiency (Addison disease) is associated with local destruction of all zones of the adrenal cortex and results in both glucocorticoid and mineralocorticoid deficiency if the insufficiency is bilateral; common symptoms and signs are listed in Table 32.3. Autoimmune disease is the most common cause of primary (nonexogenous) bilateral ACTH deficiency in the United States, whereas tuberculosis is the most common cause worldwide. Tuberculosis is associated not only with decreased adrenal function, but also large adrenal glands, which are a common finding in sarcoidosis, histoplasmosis, amyloidosis, metastatic malignant disease, heparin-induced thrombocytopenia, and adrenal hemorrhage. Further, destruction or injury by trauma, human immunodeficiency virus (HIV), and other infections (e.g., cytomegalovirus, mycobacteria, and fungi) is being recognized more frequently.

Autoimmune destruction of the adrenal glands may be associated with other autoimmune disorders, such as some forms of type 1 diabetes and Hashimoto thyroiditis. Enzymatic defects in cortisol synthesis cause glucocorticoid insufficiency, compensatory elevations in ACTH, and congenital adrenal hyperplasia. Because adrenal insufficiency usually develops slowly, such patients are subject to marked pigmentation (from excess ACTH trying to stimulate an unproductive adrenal gland) and cardiopenia (secondary to chronic hypotension).

Secondary adrenal insufficiency occurs when ACTH secretion is deficient, often because of a pituitary or hypothalamic tumor. Treatment of pituitary tumors by surgery or radiation therapy may result in hypopituitarism and subsequent adrenal failure.

If unstressed, glucocorticoid-deficient patients usually have no perioperative problems. However, acute adrenal crisis (addisonian crisis) can occur when even a minor stress is present (e.g., upper respiratory infection). Preparation of such a patient for anesthesia and surgery should include treatment of hypovolemia, hyperkalemia, and hyponatremia. Because these patients cannot respond to stressful situations, it was traditionally recommended that they be given a stress dose of glucocorticoids (≈200 mg hydrocortisone/day) perioperatively. However, Symreng and colleagues gave 25 mg of hydrocortisone phosphate intravenously to adults at the start of the operative procedure, followed by 100 mg intravenously over the next 24 hours.[50] Because using the minimum drug dose that would produce an appropriate effect is desirable, this latter regimen seems attractive. Such a regimen has proved to be as successful as a regimen using maximum doses (≈300 mg hydrocortisone/day). Thus we now recommend giving the patient's usual daily dose plus 50 to 100 mg of hydrocortisone before surgical incision and 25 to 50 mg of hydrocortisone every 8 hours for 24 to 48 hours, depending on the type and duration of surgery.[47b]

Mineralocorticoid Deficiency. Hypoaldosteronism, a less common condition, can be congenital, can occur after unilateral adrenalectomy, or be a consequence of prolonged heparin administration, long-standing diabetes, or renal failure. Nonsteroidal inhibitors of prostaglandin synthesis may also inhibit renin release and exacerbate this condition in patients with renal insufficiency. Plasma renin activity is lower than normal and fails to increase appropriately in response to sodium restriction or diuretic drugs. Most symptoms are caused by hyperkalemic acidosis rather than hypovolemia; in fact, some patients are hypertensive. These patients can have severe hyperkalemia, hyponatremia, and myocardial conduction defects. These defects can be treated successfully by administering mineralocorticoids (9α-fluorocortisol, 0.05-0.1 mg/day) preoperatively. Doses must be carefully titrated and monitored to avoid an increase in hypertension.

Patients Taking Steroids for Other Reasons

Perioperative Stress and the Need for Corticoid Supplementation. The adrenal responses of normal patients to the perioperative period, as well as the responses of patients taking steroids for other diseases, indicate the following:

1. Perioperative stress is related to the degree of trauma and the depth of anesthesia. Deep general or regional anesthesia delays the usual intraoperative glucocorticoid surge to the postoperative period.
2. A few patients with suppressed adrenal function will have perioperative cardiovascular problems if they do not receive supplemental steroids perioperatively.
3. Although a patient who takes steroids on a long-term basis may become hypotensive perioperatively; glucocorticoid or mineralocorticoid deficiency is seldom the cause. Longer duration and higher home steroid dose increase the likelihood of deficiency.[47b]
4. Acute adrenal insufficiency rarely occurs, but can be life-threatening.
5. Giving these patients steroid coverage equivalent to 100 mg of hydrocortisone perioperatively has little risk.[47b]

In a well-controlled study of glucocorticoid replacement in nonhuman primates, the investigators clearly defined the life-threatening events that can be associated with inadequate perioperative corticosteroid replacement.[48] In this study, adrenalectomized primates and sham-operated controls were given physiologic doses of steroids for 4 months. The animals were then randomly allocated to groups that received subphysiologic (one-tenth of the normal cortisol production), physiologic, or supraphysiologic (10 times the normal cortisol production) doses of cortisol for 4 days preceding abdominal surgery (cholecystectomy). The group given subphysiologic doses of steroid perioperatively had a significant increase in postoperative mortality. Death rates for the physiologic and supraphysiologic replacement groups were the same and did not differ from the rate for sham-operated controls. Death in the subphysiologic replacement group was related to severe hypotension associated with a significant decrease in systemic vascular resistance and a reduced left ventricular stroke work index. Filling pressures of the heart were unchanged when compared with those in control animals. No evidence of hypovolemia or severe congestive heart failure (CHF) was observed. Despite the low systemic vascular resistance, the animals did not become tachycardic. All these responses are compatible with the previously documented interaction of glucocorticoids and catecholamines, and thus suggest that glucocorticoids mediate catecholamine-induced increases in cardiac contractility and maintenance of vascular tone.

The investigators used a sensitive measure of wound healing involving accumulation of hydroxyproline. All treatment groups, including the group given supraphysiologic doses of glucocorticoids, had the same capacity for wound healing. Furthermore, perioperative administration of supraphysiologic doses of corticosteroids produced no adverse metabolic consequences.

This study confirmed long-standing intuitive impressions concerning patients who had inadequate adrenal function as a result of either underlying disease or administration of exogenous steroids—inadequate replacement of corticosteroids can lead to addisonian crisis and increased mortality, whereas the administration of supraphysiologic doses of steroids for a short time perioperatively can be safe. It is clear that inadequate corticosteroid coverage can cause death, but what is not so clear is what dose of steroid should be recommended for replacement therapy. Yong and colleagues reviewed the randomized controlled trials for a Cochrane Systemic Review and reported only two trials involving 37 patients that met the inclusion criteria.[51] These studies reported that supplemental perioperative steroids were not required during surgery for patients with adrenal insufficiency, but neither study reported any adverse effects or complications in the intervention or control groups. The authors concluded that they were unable to support or refute the use of supplemental perioperative steroids for patients with adrenal insufficiency during surgery. Because the risk is low and the benefit is high, physicians should consider providing supplementation for any patient who has received steroids within a year.[48,50]

How can one determine when adrenal responsiveness has returned to normal? The morning plasma cortisol level does not reveal whether the adrenal cortex has recovered sufficiently to ensure that cortisol secretion will increase adequately to meet the demands of stress. Inducing hypoglycemia with insulin has been advocated as a sensitive test of pituitary-adrenal competence, but it is impractical and is probably a more dangerous practice than simply administering glucocorticoids. If the plasma cortisol concentration is measured during acute stress, a value of greater than 25 μg/dL assuredly (and a value >15 μg/dL probably) indicates normal pituitary-adrenal responsiveness. In another test of pituitary-adrenal sufficiency, the baseline plasma cortisol level is determined. Then, 250 μg of synthetic ACTH (cosyntropin) is given, and plasma cortisol is measured 30 to 60 minutes later. An increase in plasma cortisol of 6 to 20 μg/dL or more is normal.[52,53] A normal response indicates recovery of pituitary-adrenal axis function. A lesser response usually indicates pituitary-adrenal insufficiency, possibly requiring perioperative supplementation with steroids.[53a]

Under perioperative conditions, the adrenal glands secrete 116 to 185 mg of cortisol daily. Under maximum stress, they may secrete 200 to 500 mg/day. Good correlation exists between the severity and duration of the operation and the response of the adrenal gland. "Major surgery" would be represented by procedures such as laparoscopic colectomy and "minor surgery" by procedures such as herniorrhaphy. In a study of 20 patients during major surgery, the mean maximal concentration of cortisol in plasma was 47 μg/dL (range, 22-75 μg/dL). Values remained higher than 26 μg/dL for a maximum of 72 hours postoperatively. During minor surgery, the mean maximal concentration of cortisol in plasma was 28 μg/dL (range, 10-44 μg/dL).

Although the precise amount required has not been established, we usually intravenously administer the maximum amount of glucocorticoid that the body manufactures in response to maximal stress (i.e., approximately 200 mg/day of hydrocortisone).[53b] For minor surgical procedures, we usually give hydrocortisone intravenously, 50 to 100 mg/day. Unless infection or some other perioperative complication develops, we decrease this dose by approximately 50%/day until the standard home dose is resumed. For major surgical procedures, we usually give 50 mg every 6 hours to 100 mg every 8 hours. Again unless a complication develops, this is decreased 50%/day until the standard home dose is resumed.[53b]

Risks of Supplementation. Rare complications of perioperative steroid supplementation include aggravation of hypertension, fluid retention, inducement of stress ulcers, and psychiatric disturbances. Two possible complications of short-term perioperative supplementation with glucocorticoids are abnormal wound healing and an increased rate of infections. This evidence is inconclusive, however, because it relates to short-term glucocorticoid administration and not to long-term administration of glucocorticoids with increased doses at times of stress. In contrast to a deleterious effect of perioperative glucocorticoid administration on wound healing in rats, a study involving primates suggested that large doses of glucocorticoids, administered perioperatively, do not impair sensitive measures of wound healing.[48] An overall assessment of these results suggests that short-term perioperative supplementation with steroids has a small but definite deleterious effect on wound healing that is perhaps partially reversed by topical administration of vitamin A.

Information on the risk of infection from perioperative glucocorticoid supplementation is also unclear as there are no controlled trials addressing these effects. In many studies of long-term use by patients and supplementation, no increased risk of serious infections was reported with long-term use of steroids alone. Data indicate that the risk of infection in a patient taking steroids on a long-term basis is real, but whether perioperative supplementation with steroids increases that risk is not clear.

Adrenal Cortex Function in Older Adults

Production of androgens by the adrenal gland progressively decreases with age; this change has no known implications for anesthesia. Plasma levels of cortisol are unaffected by increasing age. Levels of CBG are also unaffected by age, a finding suggesting that a normal fraction of free cortisol (1%-5%) is present in older patients. Older patients have a progressively impaired ability to metabolize and excrete glucocorticoids. In normal individuals, the quantity of 17-hydroxycorticosteroids excreted is reduced by half by the seventh decade. This decreased excretion undoubtedly reflects the reduced renal function that occurs with aging. When excretion of cortisol metabolites is expressed as a function of creatinine clearance, the age difference disappears. Further reductions in cortisol clearance may reflect impaired hepatic metabolism of circulating cortisol.

The rate of secretion of cortisol is 30% slower in older adults. This reduced secretion may be an appropriate compensatory mechanism for maintaining a normal cortisol level in the presence of decreased hepatic and renal clearance of cortisol. The reduced cortisol production can be overcome during periods of stress, and even extremely old patients (>100 years old) display an entirely normal adrenal response to the administration of ACTH and to stresses such as hypoglycemia.

Both underproduction and overproduction of glucocorticoids are generally considered diseases of younger individuals. The highest incidence of Cushing disease of either pituitary or adrenal origin occurs during the third decade of life. The most common cause of spontaneous Cushing disease is benign pituitary adenoma. However, in patients older than 60 years in whom Cushing disease develops, the most likely cause is adrenal carcinoma or ectopic ACTH production from tumors usually located in the lung, pancreas, or thymus.

ADRENAL MEDULLARY SYMPATHETIC HORMONE EXCESS: PHEOCHROMOCYTOMA

Less than 0.1% of all cases of hypertension are caused by pheochromocytomas, or catecholamine-producing tumors derived from chromaffin tissue.[54] Nevertheless, these tumors are clearly important to the anesthesiologist as previously 25% to 50% of hospital deaths in patients with pheochromocytoma occurred during induction of anesthesia or during operative procedures for other causes.[55] This high mortality has been reduced with the improvements in anesthesia management during our current era.[55a] Although usually found in the adrenal medulla, these vascular tumors can occur anywhere (referred to as paragangliomas), with a proportion of up to 20%.[55b] Malignant spread, which occurs in less than 15% of pheochromocytomas, usually proceeds to venous and lymphatic channels with a predisposition for the liver. This tumor is occasionally familial or part of the multiglandular-neoplastic syndrome known as multiple endocrine adenoma type IIa or type IIb, and is manifested as an autosomal dominant trait. Type IIa consists of medullary carcinoma of the thyroid, parathyroid adenoma or hyperplasia, and pheochromocytoma. What used to be called type IIb is now often called pheochromocytoma in association with phakomatoses such as von Recklinghausen neurofibromatosis and von Hippel–Lindau disease with cerebellar hemangioblastoma. Frequently, bilateral tumors are found in the familial form. Localization of tumors can be achieved by MRI or CT, metaiodobenzylguanidine nuclear scanning, ultrasonography, or intravenous pyelography (in decreasing order of combined sensitivity and specificity).

Symptoms and signs that may be solicited before surgery or procedures and are suggestive of pheochromocytoma are as follows: excessive sweating; headache; hypertension; orthostatic hypotension; previous hypertensive or arrhythmic response to induction of anesthesia or to abdominal examination; paroxysmal attacks of sweating, headache, tachycardia, and hypertension; glucose intolerance; polycythemia; weight loss; and psychological abnormalities. In fact, the occurrence of combined symptoms of paroxysmal headache, sweating, and hypertension is probably a more sensitive and specific indicator than any one biochemical test for pheochromocytoma (Table 32.4).

The value of preoperative and preprocedure adrenergic receptor blocking drugs probably justifies their use as these drugs may reduce the perioperative complications of hypertensive crisis, the wide arterial blood pressure fluctuations during tumor manipulation (especially until venous drainage is obliterated), and the myocardial dysfunction. Mortality is decreased with resection of pheochromocytoma (from 40% to 60% to the current 0% to 6%) when adrenergic receptor blockade is introduced as preoperative and preprocedure preparatory therapy for such patients.[56-60]

α-Adrenergic receptor blockade with prazosin or phenoxybenzamine restores intravascular plasma volume by counteracting the vasoconstrictive effects of high levels of catecholamines. This reexpansion of intravascular fluid volume is often followed by a decrease in hematocrit. Because some patients may be very sensitive to the effects of phenoxybenzamine, this drug should initially be

TABLE 32.4 Characteristics of Tests for Pheochromocytoma

			LIKELIHOOD RATIO	
Test/Symptoms	**Sensitivity (%)**	**Specificity (%)**	**Positive Result***	**Negative Result†**
Vanillylmandelic acid excretion	81	97	27.0	0.20
Catecholamine excretion	82	95	16.4	0.19
Metanephrine excretion	83	95	16.6	0.18
Abdominal computed tomography	92	80	4.6	0.10
Concurrent paroxysmal hypertension, headache, sweating, and tachycardia‡	90	95	18.0	0.10

*The ratio representing the likelihood of a positive result is obtained by dividing the sensitivity by 1 and then subtracting the specificity.
†The ratio representing the likelihood of a negative result is obtained by subtracting the sensitivity from 1 and the dividing by the specificity.
‡Data for concurrent paroxysmal symptoms are best estimates from available data.
Modified from Pauker SG, Kopelman RI. Interpreting hoofbeats: can Bayes help clear the haze? *N Engl J Med.* 1992;327:1009–1013.

given in doses of 20 to 30 mg/70 kg orally once or twice a day. Most patients usually require 60 to 250 mg/day. The Endocrine Society Task Force guidelines from 2014 recommend α-adrenergic receptor blockade for all patients with active tumors.[60a] The efficacy of therapy should be judged by the reduction in symptoms and stabilization of arterial blood pressure. For patients who have carbohydrate intolerance because of inhibition of insulin release mediated by α-adrenergic receptor stimulation, α-adrenergic receptor blockade may reduce fasting blood glucose levels. For patients who exhibit ST-T changes on the ECG, long-term preoperative and preprocedure α-adrenergic receptor blockade (1-6 months) has produced ECG and clinical resolution of catecholamine-induced myocarditis.[56,57,59-63]

β-Adrenergic receptor blockade with propranolol is suggested for patients who have persistent arrhythmias or tachycardia,[56,57,59-63] the reason being that these conditions can be precipitated or aggravated by α-adrenergic receptor blockade. It is important to remember that β-adrenergic receptor blockade should not be used without concurrent α-adrenergic receptor blockade lest the vasoconstrictive effects of the latter go unopposed and thereby increasing the risk of malignant hypertension.

The optimal duration of preoperative therapy with α-adrenergic receptor blockade has not been well studied. The Endocrine Society Task Force guidelines from 2014 recommend α-adrenergic receptor blockade at least 7 to 14 days prior to surgery; however, most centers report a preoperative treatment duration of 2 to 6 weeks.[19] Most patients will require 10 to 14 days, as judged by the time needed to stabilize arterial blood pressure and ameliorate symptoms. The Endocrine Society Task Force guidelines further recommended a high sodium diet and fluid intake to reverse the catecholamine-induced volume contraction.[63a] Because the tumor spreads slowly, little is lost by waiting until medical therapy has optimized the patient's preoperative condition. The following criteria are reasonable for assessing the adequacy of treatment:

1. No in-hospital arterial blood pressure reading higher than 165/90 mm Hg should be evident for 48 hours preoperatively.
2. Orthostatic hypotension is acceptable as long as arterial blood pressure when the patient is standing is not less than 80/45 mm Hg.
3. The ECG should be free of ST-T changes that are not permanent.
4. No more than one premature ventricular contraction (PVC) should occur every 5 minutes.

Other drugs, including prazosin, calcium channel blocking drugs, clonidine, dexmedetomidine, and magnesium, have also been used to achieve suitable degrees of α-adrenergic blockade preoperatively. Multiple case series have confirmed the clinical utility of this approach in adults before tumor excision, including in a hemodynamic catecholamine crisis.[64] Magnesium therapy has shown efficacy for the resection of pheochromocytoma or paraganglioma during pregnancy. The dosing of magnesium for the management of pheochromocytoma has been reviewed elsewhere.[65]

The key clinical components of ideal patient care include optimal preoperative preparation, slow and controlled induction of anesthesia, and good communication among members of the perioperative team. Virtually all anesthetic drugs and techniques (including isoflurane, sevoflurane, sufentanil, remifentanil, fentanyl, and regional anesthesia) have been used with success, although all drugs studied were associated with a high rate of transient intraoperative arrhythmias.[59]

Because of ease of use, the preference is to give phenylephrine for hypotension and nitroprusside or nicardipine for hypertension. Phentolamine has too long an onset and duration of action. Painful or stressful events such as intubation often cause an exaggerated stress response in less than perfectly anesthetized patients who have pheochromocytoma. This response is caused by release of catecholamines from nerve endings that are "loaded" by the reuptake process. Such stresses may result in catecholamine levels of 200 to 2000 picograms (pg)/mL in normal patients. For a patient with pheochromocytoma, even simple stress can lead to blood catecholamine levels of ten times normal. However, infarction of a tumor, with release of products onto peritoneal surfaces, or surgical pressure causing release of products, can result in blood levels of 200,000 to 1,000,000 pg/mL—a situation that should be anticipated and avoided (if possible ask for a stay of surgery to increase vasodilator infusion). Once the venous supply is secured and if intravascular volume is normal, normal arterial blood pressure usually results. However, some patients may become hypotensive and occasionally require catecholamine infusions. Vasopressin has also been used for hemodynamic rescue in catecholamine-resistant vasoplegic shock after resection of a massive pheochromocytoma.[66] On rare occasion, patients remain hypertensive intraoperatively. Postoperatively, approximately 50% of patients remain hypertensive for 1 to 3 days and initially have markedly increased but declining plasma catecholamine levels—at which time all but 25% will become normotensive. Other family members should be advised to inform their future anesthesiologist about the potential for such familial disease.

HYPOFUNCTION OR ABERRATION IN FUNCTION OF THE SYMPATHETIC NERVOUS SYSTEM (DYSAUTONOMIA)

Disorders of the sympathetic nervous system include Shy-Drager syndrome, Riley-Day syndrome, Lesch-Nyhan syndrome, Gill familial dysautonomia, diabetic dysautonomia, and the dysautonomia of spinal cord transection.

Although individuals can function well without an adrenal medulla, a deficient peripheral sympathetic nervous system occurring late in life poses major problems; nevertheless, perioperative sympathectomy or its equivalent is often recommended.[67-73] A primary function of the sympathetic nervous system appears to be regulation of arterial blood pressure and intravascular fluid volume during changing of body position. Common features of all the syndromes with hypofunction of the sympathetic nervous system are orthostatic hypotension and decreased beat-to-beat variability in heart rate. These conditions can be caused by deficient intravascular volume, deficient baroreceptor function (as also occurs in carotid artery disease[74]), abnormalities in CNS function (as in Wernicke or Shy-Drager syndrome), deficient neuronal stores of norepinephrine (as in idiopathic orthostatic hypotension[75] and diabetes), or deficient release of norepinephrine (as in traumatic spinal cord injury[76]). These patients may have a compensatory upregulation of available adrenergic receptors causing an exaggerated response to sympathomimetic drugs. In addition to other abnormalities, such as retention of urine or feces and deficient heat exchange, hypofunction of the sympathetic nervous system is often accompanied by renal amyloidosis. Thus electrolyte and intravascular fluid volume status should be assessed preoperatively. Because many of these patients have cardiac abnormalities, cardiac function and intravascular volume status may require invasive assessment with echocardiography, central venous catheter, or a pulmonary artery catheter per the treating physician's discretion.

Because the functioning of the sympathetic nervous system is not predictable in these patients, slow and controlled induction of anesthesia and treatment of sympathetic excess or deficiency should be initiated through titratable direct-acting vasodilators (nicardipine/nitroprusside), vasoconstrictors (phenylephrine/norepinephrine), chronotropes (isoproterenol), or negative chronotropes (esmolol). A 20% perioperative mortality rate for 2600 patients after spinal cord transection has been reported, thus indicating that such patients are difficult to manage and deserve particularly close attention.

After reviewing 300 patients with spinal cord injuries, Kendrick and coworkers concluded that autonomic hyperreflexia syndrome does not develop if the lesion is below spinal dermatome T7.[77] If the lesion is above that level (splanchnic outflow), 60% to 70% of patients experience extreme vascular instability. The trigger to this instability, a mass reflex involving noradrenergic release and motor hypertonus, can be a cutaneous, proprioceptive, or visceral stimulus (a full bladder is a common initiator). The sensation enters the spinal cord and causes a spinal reflex, which in normal persons is inhibited from above. Sudden increases in arterial blood pressure are sensed in the pressure receptors of the aorta and carotid sinus. The resulting vagal hyperactivity produces bradycardia, ventricular ectopia, or various degrees of heart block. Reflex vasodilation may occur above the level of the lesion and result in flushing of the head and neck. In the acute injury period, modest therapeutic hypothermia may provide benefit but many note that further large randomized trials are needed; the anesthesiologist must be vigilant to avoid hyperthermia and maintain normothermia—hypothermia during procedures.[77a]

Depending on the length of time since spinal cord transection, other abnormalities may occur. In the short term (i.e., <3 weeks from the time of spinal injury), retention of urine and feces is common and, through elevation of the diaphragm, may affect respiration. Hyperesthesia is present above the lesion; reflexes and flaccid paralysis are present below the lesion. The intermediate period (3 days to 6 months) is marked by a hyperkalemic response to depolarizing drugs.[78] The chronic phase is characterized by return of muscle tone, Babinski sign, and, frequently, the occurrence of hyperreflexia syndromes (e.g., mass reflex [see earlier]).

Thus in addition to meticulous attention to perioperative intravascular volume and electrolyte status, the anesthesiologist should know—by history taking, physical examination, and laboratory data—the status of the patient's myocardial conduction (as revealed by the ECG), the status of renal functioning (by noting the ratio of creatinine to blood urea nitrogen [BUN]), and the condition of the respiratory muscles (by determining the ratio of forced expiratory volume in 1 second to forced vital capacity). The anesthesiologist may also obtain a chest radiograph if atelectasis or pneumonia is suspected on the basis of history taking or the physical examination. Temperature control, the presence of bone fractures or decubitus ulcers, and normal functioning of the urination and defecation systems must be assessed.

THYROID DYSFUNCTION

The major thyroid hormones are thyroxine (T_4), a prohormone product of the thyroid gland, and the more potent 3,5,3-triiodothyronine (T_3), a product of both the thyroid and extrathyroidal enzymatic deiodination of T_4. Under normal circumstances, approximately 85% of T_3 is produced outside the thyroid gland. Production of thyroid secretions is maintained by secretion of thyroid-stimulating hormone (TSH) in the pituitary, which in turn is regulated by secretion of thyrotropin-releasing hormone (TRH) in the hypothalamus. Secretion of TSH and TRH appears to be negatively regulated by T_4 and T_3. Many investigators believe that all effects of thyroid hormones are mediated by T_3 and that T_4 functions only as a prohormone.

TABLE 32.5 Biochemical Measurements of Thyroid Function That Account for Variation in Production of Thyroxine-Binding Globulin

	EXAMPLES OF NORMAL THYROID STATUS*					
	FT$_4$E	**=**	**T$_4$**	**×**	**THBR**	**TSH**
Normal	0.19 (0.12-0.25)	=	0.6 (0.4-0.9)	×	31% (25%-35%)	0.2 (0.2-0.8)
During use of oral contraceptives	0.19	=	1.3	×	15%	0.3
During use of corticosteroids	0.18	=	0.3	×	60%	0.3

*FT$_4$E is the free T$_4$ (thyroxine) estimate. It is usually obtained by multiplying the total T$_4$ concentration (the free amount and the amount bound to protein) by the thyroid hormone–binding ratio (THBR, formerly called the resin T$_3$ uptake). THBR is a measure of the bound thyroid hormone–binding protein. TSH is the thyroid-stimulating hormone secreted by the pituitary in the negative feedback loop. (TSH increases when FT$_4$E is low in hypothyroidism.)

BOX 32.2 **Factors Influencing Serum Levels of Thyroxine-Binding Globulin**

Conditions Increasing Serum Levels

- Use of oral contraceptives
- Pregnancy
- Use of estrogen
- Infectious hepatitis
- Chronic active hepatitis
- Neonatal state
- Acute intermittent porphyria
- Inherited conditions

Conditions Decreasing Serum Levels

- Testosterone
- Use of corticosteroids
- Severe illness
- Cirrhosis
- Nephrotic syndrome
- Inherited conditions

Because T$_3$ has greater biologic effect than does T$_4$, one would expect the diagnosis of thyroid disorders to be based on levels of T$_3$. However, this is not usually the case. The diagnosis of thyroid disease is confirmed by one of several biochemical measurements: levels of free T$_4$ or total serum concentrations of T$_4$ and the "free T$_4$ estimate." This estimate is obtained by multiplying total T$_4$ (free and bound) by the thyroid-binding ratio (formerly called resin T$_3$ uptake) (Table 32.5). Free T$_4$ can be accurately measured by many laboratories, this direct measurement of free T$_4$ obviates the need to account for changes in binding protein synthesis and affinity caused by other conditions. The T$_3$-binding ratio measures the extra quantity of serum protein-binding sites. This measurement is necessary because thyroxine-binding globulin (TBG) levels are abnormally high during pregnancy, hepatic disease, and estrogen therapy (all of which would elevate the total T$_4$ level; Box 32.2). Reliable interpretation of measurements of the total hormone concentration in serum necessitates data on the percentage of bound hormone. The thyroid hormone–binding ratio test provides this information. In this test, iodine-labeled T$_3$ is added to a patient's serum and is allowed to reach an equilibrium binding state. A resin is then added that binds the remaining radioactive T$_3$. Resin uptake is greater if the patient has fewer TBG-binding sites. In normal patients, resin T$_3$ uptake (the thyroid hormone–binding ratio) is 25% to 35%. When serum TBG is elevated, the thyroid hormone–binding ratio is diminished (see Table 32.5). When serum TBG is diminished, as in nephrotic syndrome, in conditions in which glucocorticoids are increased, or in chronic liver disease, the thyroid hormone–binding ratio is increased.

The free T$_4$ estimate and the free T$_3$ estimate are frequently used as measures of a patient's serum T$_4$ and T$_3$ hormone concentrations, respectively. To obtain these estimates, the concentration of total serum T$_4$ or total serum T$_3$ is multiplied by the measured thyroid hormone–binding ratio. Values of these two indices are normal in the event of a primary alteration in binding but not with an alteration in secretion of thyroid hormone.

Hyperthyroidism can be diagnosed by measuring levels of TSH after the administration of TRH. Although administering TRH normally increases TSH levels in blood, even a small increase in the T$_4$ or T$_3$ level in blood abolishes this response. Thus a subnormal or absent serum TSH response to TRH is a very sensitive indicator of hyperthyroidism. In one group of disorders involving hyperthyroidism, serum TSH levels are elevated in the presence of elevated levels of free thyroid hormone.

Measurement of the α-subunit of TSH has been helpful in identifying the rare patients who have a pituitary neoplasm and who usually have increased α-subunit concentrations. Some patients are clinically euthyroid in the presence of elevated levels of total T$_4$ in serum. Certain drugs, notably propranolol, glucocorticoids, and amiodarone, block the conversion of T$_4$ to T$_3$ and thereby elevate T$_4$ levels. Severe illness also slows this conversion, termed "sick thyroid" in a critical-illness setting. Levels of TSH are often high in situations in which the rate of conversion is decreased. In hyperthyroidism, cardiac function and responses to stress are abnormal; return of normal cardiac function parallels the return of TSH levels to normal.

Hyperthyroidism

Although hyperthyroidism is usually caused by the multinodular diffuse enlargement in Graves disease (also associated with disorders of the skin or eyes, or both), it can also occur with pregnancy, thyroiditis, thyroid adenoma, choriocarcinoma, or TSH-secreting pituitary adenoma. Five percent of women have thyrotoxic effects 3 to 6 months postpartum and tend to have recurrences with subsequent pregnancies. Major manifestations of hyperthyroidism are weight loss, diarrhea, warm and moist skin, weakness of large muscle groups, menstrual abnormalities, osteopenia, nervousness, jitteriness, intolerance to heat, tachycardia, cardiac arrhythmias, mitral valve prolapse, and heart failure. When the thyroid is functioning abnormally, the cardiovascular system is most at risk. When diarrhea is severe, the associated dehydration and electrolyte abnormalities should be corrected preoperatively. Mild anemia, thrombocytopenia, increased serum alkaline phosphatase, hypercalcemia, muscle wasting, and bone loss frequently occur in hyperthyroidism. Muscle disease usually involves the proximal large muscle groups; it has not been reported to cause respiratory muscle paralysis. In the apathetic form of hyperthyroidism (seen most commonly in persons >60 years old), cardiac effects predominate and include tachycardia, irregular heart rhythm, atrial fibrillation (in 10%), heart failure, and occasionally, papillary muscle dysfunction.

Although β-adrenergic receptor blockade can control the heart rate, its use is challenging in the setting of heart failure. However, a decreasing heart rate may improve heart-pumping function. Thus hyperthyroid patients who have fast ventricular rates and in heart failure, requiring emergency surgery, can be safely given short-acting β-blockers guided by clinical response. If slowing the heart rate with a small dose of esmolol (50 μg/kg) does not aggravate the heart failure, the physician should administer more esmolol, and titrate to effect. Antithyroid medications include propylthiouracil and methimazole, both of which decrease the synthesis of T_4 and may enhance remission by reducing TSH receptor antibody levels (the primary pathologic mechanism in Graves disease). Propylthiouracil also decreases the conversion of T_4 to the more potent T_3. However, the literature indicates a trend toward preoperative preparation with propranolol and iodides alone.[79] This approach is quicker (i.e., 7-14 days vs. 2-6 weeks); it shrinks the thyroid gland, as does the more traditional approach; it decreases conversion of the prohormone T_4 into the more potent T_3; and it treats symptoms but may not correct abnormalities in left ventricular function. Regardless of the approach, antithyroid drugs should be administered on a long-term basis and on the morning of the surgical procedure. If emergency surgery is necessary before the euthyroid state is achieved, if subclinical hyperthyroidism progresses without adequate treatment, or if hyperthyroidism is out of control intraoperatively, intravenous administration of esmolol, 50 to 500 μ/kg, could be titrated to restore a normal heart rate (assuming the absence of heart failure). In addition, intravascular fluid volume and electrolyte balance should be restored. However, administering propranolol or esmolol does not always prevent "thyroid storm." No specific anesthetic drug is preferred for surgical patients who have hyperthyroidism.

A patient with a large goiter and an obstructed airway can be managed in the same way as any other patient with a problematic airway. In this type of case, reviewing CT scans of the neck preoperatively may provide valuable information regarding the extent of compression. Maintenance of anesthesia usually presents little difficulty. Postoperatively, extubation of the trachea should be performed under optimal circumstances for reintubation in the event that tracheomalacia (the tracheal rings have been weakened and the trachea collapses) developed.

Of the many possible postoperative complications including: nerve injury, bleeding, metabolic abnormalities, and thyroid storm (discussed in the next section); bilateral recurrent laryngeal nerve trauma and hypocalcemic tetany are the most feared. Bilateral recurrent laryngeal nerve injury (secondary to trauma or edema) causes stridor and laryngeal obstruction as a result of unopposed adduction of the vocal cords and closure of the glottic aperture. Immediate endotracheal intubation is required, usually followed by tracheostomy to ensure an adequate airway. Fortunately, Lahey Clinic records indicate that this rare complication occurred only once in more than 30,000 thyroid operations. Unilateral recurrent nerve injury often goes unnoticed because of compensatory overadduction of the uninvolved cord. However, we often test vocal cord function before and after this operation by asking the patient to say "e" or "moon." Unilateral nerve injury is characterized by hoarseness, whereas aphonia characterizes bilateral nerve injury. Selective injury to the adductor fibers of both recurrent laryngeal nerves leaves the abductor muscles relatively unopposed, and pulmonary aspiration is a risk. Selective injury to the abductor fibers leaves the adductor muscles relatively unopposed, and airway obstruction can occur.

The intimate involvement of the parathyroid gland with the thyroid gland can result in inadvertent hypocalcemia during surgery for thyroid disease. Complications related to hypocalcemia are discussed in the later section on this disorder.

Because postoperative hematoma can compromise the airway, neck and wound dressings are placed in a crossing fashion (rather than vertically or horizontally) and should be examined for evidence of bleeding before a patient is discharged from the recovery room.

Thyroid Storm

Thyroid storm is the name for the clinical diagnosis of a life-threatening illness in a patient whose hyperthyroidism has been severely exacerbated by illness or surgery. Thyroid storm is characterized by hyperthermia or pyrexia, tachycardia, and striking alterations in consciousness. Its clinical appearance is similar to malignant hyperthermia, pheochromocytoma, and neuroleptic malignant syndrome, further complicating the differential.[79a] No laboratory tests are diagnostic of thyroid storm, and the precipitating (nonthyroidal) cause is the major determinant of survival. Therapy can include blocking the synthesis of thyroid hormones by administering antithyroid drugs and the release of preformed hormone with iodine. Blocking the sympathetic nervous system symptoms with reserpine, α- and β-receptor antagonists, or α_2 drugs may be exceedingly hazardous and requires skillful management with constant monitoring of the critically ill patient.

Thyroid dysfunction, either hyperthyroidism or hypothyroidism, develops in more than 10% of patients treated with the antiarrhythmic agent amiodarone.[80] Approximately 35% of the drug's weight is iodine, and a 200-mg tablet releases approximately 20 times the optimal daily dose of iodine. This iodine can lead to reduced synthesis of T_4 or increased synthesis. In addition, amiodarone inhibits the conversion of T_4 to the more potent T_3. These patients receiving amiodarone are in need of special attention preoperatively and intraoperatively, not just because of the arrhythmia that led to such therapy, but to ensure that no perioperative dysfunction or surprises result from unsuspected thyroid hyperfunction or hypofunction.[81]

Hypothyroidism

Hypothyroidism is a common disease that has been detected in 5% of a large population in Great Britain, in 3% to 6% of a healthy older population in Massachusetts, in 4.5% of a medical clinic population in Switzerland, and in 8.5% of a large Turkish population presenting to an anesthesiology preoperative clinic.[81a] The apathy and lethargy that often accompany hypothyroidism frequently delay its diagnosis, thus the perioperative period may be the first opportunity to spot many such hypothyroid patients. However, hypothyroidism is usually subclinical, serum concentrations of thyroid hormones are in the normal range, and only serum TSH levels are elevated. The normal range of TSH is 0.3 to 4.5 milliunits/L, and TSH values of 5 to 15 milliunits/L are characteristic of this entity. In such cases, hypothyroidism may have little or no perioperative significance. However, a retrospective study of 59 mildly hypothyroid patients found that more hypothyroid patients than control subjects required prolonged postoperative intubation (9 of 59 vs. 4 of 59), had significant electrolyte imbalances (3 of 59 vs. 1 of 59), and bleeding complications (4 of 59 vs. 0 of 59).[82] Because only a few charts were examined, these differences did not reach statistical significance. In another study, overt hypothyroidism later developed in a high percentage of patients with a history of subclinical hypothyroidism.[83,84]

Overt hypothyroidism is associated with slow mental functioning, slow movement, slow reflexes, dry skin, arthralgias, carpal tunnel syndrome, periorbital edema, intolerance to cold, depression of the ventilatory responses to hypoxia and hypercapnia, impaired clearance of free water with or without hyponatremia, slow gastric emptying, sleep apnea,[85] and bradycardia. In extreme cases, cardiomegaly, heart failure, pericardial and pleural effusions can develop, often presenting as orthopnea, dyspnea, or general fatigue. Hypothyroidism is often associated with amyloidosis, which may produce an enlarged tongue, cardiac conduction abnormalities, and renal disease. Hypothyroidism decreases the anesthetic requirement slightly. The tongue may be enlarged in a hypothyroid patient even in the absence of amyloidosis, and such enlargement may hamper endotracheal intubation.

An increasing TSH level is the most sensitive indicator of failing thyroid function. Ideal preoperative and preprocedure management of hypothyroidism consists of restoring normal thyroid status: the physicians should consider administering the normal dose of levothyroxine the morning of the surgical procedure, even though these drugs have long half-lives (1.4-10 days). Reduced GI absorption of levothyroxine may occur with the coadministration of cholestyramine or aluminum hydroxide, iron, a high-bran meal, or sucralfate or colestipol. For patients in myxedema coma who require emergency surgery, liothyronine (T3 hormone) can be given intravenously (with fear of precipitating myocardial ischemia, however) while supportive therapy is undertaken to restore normal intravascular fluid volume, body temperature, cardiac function, respiratory function, and electrolyte balance.[85a]

In hypothyroidism, respiratory control mechanisms and renal fluid balance do not function normally, however, the response to hypoxia and hypercapnia, and clearance of free water normalize with thyroid replacement therapy. Drug metabolism is anecdotally reported to be slowed, and awakening times from sedatives are reported to be prolonged by hypothyroidism. However, few formal studies, and none in humans, of the pharmacokinetics and pharmacodynamics of sedatives or anesthetic drugs in this population have been published. These concerns disappear when thyroid function is normalized preoperatively. Addison disease (with its relative steroid deficiency) is more common in hypothyroidism, and some endocrinologists routinely treat patients with noniatrogenic hypothyroidism with stress doses of steroids perioperatively because both conditions are commonly caused by autoimmune responses. The possibility that this steroid deficiency exists should be considered if the patient becomes hypotensive perioperatively. Body heat mechanisms are inadequate in hypothyroid patients, so temperature should be monitored and maintained, especially in patients requiring emergency surgery. Because of an increased incidence of myasthenia gravis in hypothyroid patients, a peripheral nerve stimulator is used to guide judicious administration of muscle relaxants.

Thyroid Nodules and Carcinoma

More than 90% of thyroid nodules are benign, yet identifying malignancy in a solitary thyroid nodule is a difficult and important procedure. Male patients and patients with previous radiation therapy to the head and neck have an increased likelihood of malignant disease in their nodules. Often, needle biopsy and scanning are sufficient for the diagnosis, but occasionally excisional biopsy is needed. Papillary carcinoma accounts for more than 70% of all thyroid carcinomas. Simple excision of lymph node metastases appears to be as efficacious as radical neck procedures for the patient's survival. Follicular carcinoma, which accounts for approximately 15% of thyroid carcinomas, is more aggressive, and has a less favorable prognosis.

Medullary carcinoma, the most aggressive form of thyroid carcinoma, is associated with a familial occurrence of pheochromocytoma, as are parathyroid adenomas. For this reason, a history should be obtained from patients with a surgical scar in the thyroid region so that the possibility of occult pheochromocytoma can be assessed and excluded.

DISORDERS OF CALCIUM METABOLISM

The three substances that regulate serum concentrations of calcium, phosphorus, and magnesium are parathyroid hormone (parathyrin, PTH), calcitonin, and vitamin D, which act on bone, kidney, gut, and their own receptors. Calcium excess in blood is caused by either malignant disease or hyperparathyroidism in more than 90% of patients.[86] PTH stimulates bone resorption, inhibits renal excretion of calcium, and increases conversion to active vitamin D, three conditions that lead to hypercalcemia. Calcitonin can be considered an antagonist to PTH. Through its metabolites, vitamin D aids in the absorption of calcium, phosphate, and magnesium from the gut and facilitates the bone resorptive effects of PTH. Secretion of PTH is modulated through the calcium-sensing receptor on the cell surface of parathyroid cells. An increase in ionized calcium stimulates this receptor and thus causes a decrease in PTH secretion. Recognition of this effect has led to reevaluation of the therapy for hyperparathyroidism inasmuch as a drug upregulating this receptor's sensitivity reduces PTH levels.[87]

Hyperparathyroidism and Hypercalcemia

Primary hyperparathyroidism occurs in approximately 0.1% of the population, most commonly begins in the third to fifth decades of life, and occurs two to three times more frequently in women than in men. Primary hyperparathyroidism usually results from enlargement of a single gland, commonly an adenoma and very rarely a carcinoma. Hypercalcemia almost always develops.

Calcium is the chief mineral component of the body; it provides structure to the skeleton and performs key roles in neural transmission, intracellular signaling, blood coagulation, and neuromuscular functioning. Ninety-nine percent of the 1000 g of calcium present in the average human body is stored in the bone mineral reservoir. Fifty percent to 60% is bound to plasma proteins or is complexed with phosphate or citrate. The normal total serum calcium level is 8.6 to 10.4 mg/dL, as measured in most laboratories; though this value depends on the albumin level, noting a decline of 0.8 mg/dL for each 1 g/dL drop in albumin. Binding of calcium to albumin depends on pH: binding decreases with acidic pH and increases with alkaline pH. Serum calcium, not ionized calcium, decreases with reductions in albumin levels. Although ionized calcium is the clinically significant fraction, the cost and technical difficulties of stabilizing the electrodes used for measurement have limited the available assays. Nevertheless, PTH and vitamin D_3 work to keep the level stable within 0.1 mg/dL in any individual.

Many of the prominent symptoms of hyperparathyroidism are a result of the hypercalcemia that accompanies it. Regardless of the cause, hypercalcemia can produce any of a number of symptoms, the most prominent of which involve the renal, skeletal, neuromuscular, and GI system, including anorexia, vomiting, constipation, polyuria, polydipsia, lethargy, confusion, renal calculi, pancreatitis, bone pain, and psychiatric abnormalities. Free intracellular calcium initiates or regulates muscle contraction, release of neurotransmitters, secretion of hormones, enzyme action, and energy metabolism.

Nephrolithiasis occurs in 60% to 70% of patients with hyperparathyroidism. Sustained hypercalcemia can result in tubular and glomerular disorders, including proximal (type II) renal tubular acidosis. Polyuria and polydipsia are common complaints.

Skeletal disorders related to hyperparathyroidism are osteitis fibrosa cystica, simple diffuse osteopenia, and osteoporosis. The rate of bone turnover is five times higher in patients with hyperparathyroidism than in normal controls. Patients may have a history of frequent fractures or may complain of bone pain, especially in the anterior margin of the tibia.

Because free intracellular calcium initiates or regulates muscle contraction, neurotransmitter signaling, hormone secretion, enzyme action, and energy metabolism, abnormalities in these end organs are often symptoms of hyperparathyroidism. Patients may experience profound muscle weakness, especially in proximal muscle groups, as well as muscle atrophy. Depression, psychomotor retardation, and memory impairment may occur. Lethargy and confusion are frequent complaints.

Peptic ulcer disease is more common in these patients than in the rest of the population. Production of gastrin and gastric acid is increased. Anorexia, vomiting, and constipation may also be present.

Approximately one third of all hypercalcemic patients are hypertensive, but the hypertension usually resolves with successful treatment of the primary disease. Neither hypertension nor minimally invasive surgery seems to alter the perioperative risk associated with surgery in such patients in comparison with the usual hypertensive patients.[88,89] Even octogenarians with asymptomatic hyperparathyroidism can be operated on without mortality and with morbidity no different from that in younger individuals, thus encouraging the use of parathyroidectomy as preventive therapy.[90] Long-standing hypercalcemia can lead to calcifications in the myocardium, blood vessels, brain, and kidneys. Cerebral calcifications may cause seizures, whereas renal calcifications lead to polyuria that is unresponsive to vasopressin.[90]

The most useful confirmatory test for hyperparathyroidism is radioimmunoassay for PTH. In fact, two changes have radically reduced anesthesia involvement in the care of patients with primary hyperparathyroidism. One change, the use of the calcimimetic drug class which modulates the calcium-sensitive PTH cell receptor and thereby decreases calcium levels, has been emphasized in older individuals. The other change is use of minimally invasive approaches after imaging procedures with just local anesthesia or a cervical plexus block—as with thyroidectomy.[91,92] Most surgeons now performing minimally invasive parathyroid removal monitor PTH levels intraoperatively to determine whether the causative adenoma has been resected. The baseline PTH level should be determined before induction of anesthesia because even monitored anesthesia care increases PTH levels.[93] In hyperparathyroid patients, hormone levels are abnormal for a given level of calcium. The level of inorganic phosphorus in serum is usually low, but it may be within normal limits. Alkaline phosphatase levels are elevated if considerable skeletal involvement is present.

Glucocorticoid administration reduces the level of calcium in blood in many other conditions that cause hypercalcemia, but not usually in primary hyperparathyroidism. In sarcoidosis, multiple myeloma, vitamin D intoxication, and some malignant diseases, all of which can cause hypercalcemia, administration of glucocorticoids may lower serum calcium levels through an effect on GI absorption. This effect occurs to a lesser degree in primary hyperparathyroidism.

Hypercalcemia may also occur as a consequence of secondary hyperparathyroidism in patients who have chronic renal disease. When phosphate excretion decreases as a result of decreased nephron mass, serum calcium levels fall because of deposition of calcium and phosphate in bone. Secretion of PTH subsequently increases, and this causes the fraction of phosphate excreted by each nephron to increase. Eventually, the chronic intermittent hypocalcemia of chronic renal failure leads to chronically high levels of serum PTH and hyperplasia of the parathyroid glands—one of the entities termed secondary hyperparathyroidism.

Symptomatic primary hyperparathyroidism in patients younger than 50 years or with serum calcium levels more than 1 mg/dL higher than the upper limit of normal, a 30% or greater reduction in the glomerular filtration rate (GFR), or severe bone demineralization is usually treated surgically. If the patient refuses surgery or if other illnesses render surgery inadvisable, medical management with the calcimimetic, cinacalcet, makes management much more feasible. The difficulty with such management is that the hyperfunctioning parathyroid glands secrete more hormone as the serum calcium concentration is lowered—as

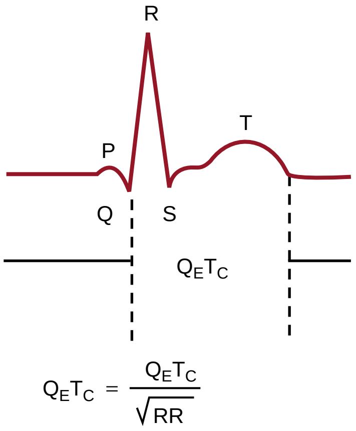

Fig. 32.3 Measurement of the QTc interval (properly termed Q_ET_C to indicate that it begins with the start of the Q wave, lasts throughout the QT interval, ends with the end of the T wave, and is corrected for heart rate). RR is the RR interval in seconds. (From Hensel P, Roizen MF. Patients with disorders of parathyroid function. *Anesthesiol Clin North Am.* 1987;5:287–291.)

though the calcium set point for feedback regulation of PTH secretion had been raised. Blanchard and colleagues demonstrated that patients with "asymptomatic" primary hyperparathyroidism have clinical improvement of their symptoms postoperatively even after 1 year, noting younger patients and those with higher preoperative calcium levels show the best improvement.[94]

Patients with moderate hypercalcemia who have normal renal and cardiovascular function present no special preoperative and preprocedure problems. The ECG can be examined preoperatively and intraoperatively for shortened PR or QT intervals (Fig. 32.3). Because severe hypercalcemia can result in substantial hypovolemia, normal intravascular volume and electrolyte status should be evaluated and then restored before anesthesia and surgery.

Management of hypercalcemia preoperatively should include (even in urgent or emergency situations) treatment of the underlying cause, a frequent strategy in surgical patients with malignancy-associated hypercalcemia. Therapy preoperatively for both malignant and nonmalignant causes of hypercalcemia include aggressive volume repletion, with the addition of diuresis only if volume overload develops. Intravenous fluid infusion rates of 250 to 500 mL/h preoperatively are commonly used to maintain urine output greater than 200 mL/h.[94a] Careful monitoring during this time is needed to avoid administration of an excessive amount of intravenous fluids, as many patients may have compromised cardiac function. In the setting of fluid overload, diuresis with furosemide can be warranted; however, evidence for benefit is limited and mainly theoreteical.[94a] Other complications of these interventions include hypomagnesemia and hypokalemia.

In emergency situations, vigorous expansion of intravascular volume usually reduces serum calcium to a safe level (<14 mg/dL). Phosphate should be given to correct hypophosphatemia because it decreases calcium uptake into bone, increases calcium excretion, and stimulates breakdown of bone. Hydration, accompanied by electrolyte repletion mainly phosphate, suffices in the management of most hypercalcemic patients. Other measures to decrease reabsorption of bone include the bisphosphonates pamidronate sodium (90 mg intravenously) and zoledronate (4 mg intravenously). Case reports note success in the setting of extreme hypercalcemia (>20 mg/dL) correction with a low calcium bath dialysate.[94b]

Calcitonin lowers serum calcium levels through direct inhibition of bone resorption. It can decrease serum calcium levels within minutes after intravenous administration. Side effects include urticaria and nausea. It is so rapid acting that it can be used to reduce calcium levels while waiting for hydration and a bisphosphonate to take effect.

It is especially important to know whether the hypercalcemia has been chronic because serious cardiac, renal, or CNS abnormalities may have resulted.

Hypocalcemia

Hypocalcemia (caused by hypoalbuminemia, hypoparathyroidism, hypomagnesemia, hypovitaminosis D, hungry bone syndrome after correction of hyperparathyroidism, anticonvulsant therapy, citrate infusion, or chronic renal disease) is not usually accompanied by a clinically evident cardiovascular disorder. The most common cause of hypocalcemia is hypoalbuminemia. In true hypocalcemia (i.e., when the free calcium concentration is low), myocardial contractility is affected, noting myocardial contractility varies directly with levels of blood ionized calcium. The clinical signs of hypocalcemia include clumsiness; convulsions; laryngeal stridor; depression; muscle stiffness; paresthesias; parkinsonism; tetany; Chvostek sign; dry and scaly skin, brittle nails, and coarse hair; low serum concentrations of calcium; prolonged QT intervals; soft tissue calcifications; and Trousseau sign.

Hypocalcemia delays ventricular repolarization, hence increasing the QTc interval (normal, 0.35-0.44 second). With electrical systole prolonged, the ventricles may fail to respond to the next electrical impulse from the sinoatrial node, with second-degree heart block resulting. Prolongation of the QT interval is a moderately reliable ECG sign of hypocalcemia, not for the population as a whole, but for the individual patient.[95] Thus monitoring the QT interval as corrected for the heart rate is a useful, but not always accurate means of monitoring hypocalcemia in any individual patient (see Fig. 32.3). Heart failure may also occur with hypocalcemia, but is rare. Because heart failure in patients with coexisting heart disease is reduced in severity when calcium and magnesium ion levels are restored to normal, these levels may be normalized preoperatively in a patient with impaired exercise tolerance or signs of cardiovascular dysfunction; normalization can be achieved intravenously over a 15-minute period if absolutely necessary. Sudden decreases in blood levels of ionized calcium (as with chelation therapy) can result in severe hypotension.

Patients with hypocalcemia may have seizures. They may be focal, petit mal, or grand mal in appearance, often indistinguishable from such seizures in the absence of hypocalcemia. Patients may also have a type of seizure called cerebral tetany, which consists of generalized tetany followed by tonic spasms. Therapy with standard anticonvulsants is ineffective and may even exacerbate these seizures (by an anti–vitamin D effect), calcium must be repleted for treatment. In long-standing hypoparathyroidism, calcifications may appear above the sella; these calcifications represent deposits of calcium in and around small blood vessels of the basal ganglia. They may be associated with a variety of extrapyramidal syndromes.

The most common cause of acquired hypoparathyroidism is surgery of the thyroid or parathyroid glands. Other causes include autoimmune disorders, therapy with iodine-131, hemosiderosis or hemochromatosis, neoplasia, and granulomatous disease. Idiopathic hypoparathyroidism has been divided into three categories: an isolated persistent neonatal form, branchial dysembryogenesis, and autoimmune candidiasis related to multiple endocrine deficiency.

Pseudohypoparathyroidism and pseudopseudohypoparathyroidism are rare hereditary disorders characterized by short stature, obesity, rounded face, and shortened metacarpals. Patients with pseudohypoparathyroidism have hypocalcemia and hyperphosphatemia despite high serum levels of PTH. These patients have a deficient end-organ response to PTH as a result of abnormalities in G-protein function.

Because treatment of hypoparathyroidism is not surgical, hypoparathyroid patients who come to the operating room are those who require surgery for unrelated conditions. Their calcium, phosphate, and magnesium levels should be measured both preoperatively and postoperatively. Patients with symptomatic hypocalcemia may be treated with intravenous calcium gluconate preoperatively. Initially, 10 to 20 mL of 10% calcium gluconate may be given at a rate of 5 mL/min. The effect on serum calcium levels is of short duration, but a continuous infusion with 10 mL/min of 10% calcium gluconate in 500 mL of solution over a period of 6 hours helps keep serum calcium at adequate levels. For severe symptoms in emergent settings, 10 mL of 10% calcium chloride may be given over 10 minutes, followed by a 10% calcium gluconate infusion. Magnesium and phosphate levels may also require normalization to normalize cardiovascular and nervous system function.

The objective of therapy is to bring the symptoms under control before the surgical procedure and anesthesia. For patients with chronic hypoparathyroidism, the objective is to keep the serum calcium level in the lower half of the normal range. A preoperative and preprocedure ECG is useful for maintaining the QTc interval. The preoperative and preprocedure QTc value may be used as a guide to the serum calcium level if rapid laboratory assessment is not possible. Changes in the calcium level may alter the duration of muscle relaxation; thus careful monitoring and titration of muscle relaxation with a twitch monitor is necessary.

The intimate involvement of the parathyroid gland with the thyroid gland can result in unintentional hypocalcemia during surgery for diseases of either organ. Because of the affinity of their bones for calcium, this relationship is crucial in patients with advanced osteitis. Internal redistribution of magnesium, calcium, or both ions may occur (into “hungry bones”) after parathyroidectomy and may cause hypomagnesemia, hypocalcemia, or both. Because the tendency to tetany increases with alkalosis, hyperventilation should be avoided. The most prominent manifestations of acute hypocalcemia are distal paresthesias and muscle spasm (tetany). Potentially fatal complications of severe hypocalcemia include laryngeal spasm and hypocalcemic seizures. The clinical sequelae of magnesium deficiency include cardiac arrhythmias (principally ventricular tachyarrhythmias), hypocalcemic tetany, and neuromuscular irritability independent of hypocalcemia (tremors, twitching, asterixis, and seizures).

In addition to monitoring total serum calcium or ionized calcium postoperatively, one can test for the Chvostek and Trousseau signs. The Chvostek sign is a contracture of the facial muscles produced by tapping the ipsilateral facial nerve at the angle of the jaw, of note this sign can be elicited in up to 15% of patients who are not hypocalcemic, an attempt should be made to elicit this sign preoperatively to ensure that its appearance is meaningful. The Trousseau sign is elicited by applying a blood pressure cuff at a level slightly above the systolic level for a few minutes. The resulting carpopedal spasm, with contraction of the fingers and inability to open the hand, stems from the increased muscle irritability in hypocalcemic states, aggravated by ischemia produced by the blood pressure cuff.

Osteoporosis

Fifty percent of women who are older than 65 years sustain an osteoporotic fracture. (Because men are living longer, osteoporosis has become an increasing problem for them, too, and reports indicate a 15% per decade hip fracture rate for men >65 years old.)[95] Men with COPD (even without steroid treatment) are at high risk for vertebral fractures. Furthermore, in either gender, each vertebral fracture is associated with up to a 10% decrease in lung capacity. Diagnosis and treatment of these conditions have increased with routine use of dual-energy x-ray absorptiometry or quantitative ultrasonography. Because T-scores and Z-scores were developed to relate changes in white postmenopausal women to those at age 21 years, care must be used in interpreting the results. Known risk factors for osteoporosis include age, relative lifetime estrogen deficiency (late menarche, amenorrhea, early menopause, nulliparity), deficiency of dietary calcium, tobacco use, increased aerobic exercise in combination with decreased weight-bearing exercise, decreased weight-bearing exercise by itself, use of soft drinks, and Asian or white ancestry. Although therapy for osteoporosis (use of biphosphates, bone mineral depositors, weight-bearing exercises, calcium, vitamin D, estrogen, and now designer estrogens that may be useful for men, such as raloxifene [Evista]) does not have major known implications for anesthesia care.[96-98] Bone fractures in such patients have occurred on movement to and from an operating table, therefore these patients should be allowed to move and position themselves when possible. Recombinant PTH and calcitonin are also used, but again, no reports of perioperative interactions have been prominent.

PITUITARY ABNORMALITIES

Anterior Pituitary Hypersecretion

The anterior pituitary gland (or master endocrine gland) consists of five identifiable types of secretory cells and hormones produced: somatotrophs (GH), corticotrophs (ACTH), lactotrophs (prolactin), gonadotrophs (luteinizing hormone and follicle-stimulating hormone), and thyrotrophs (TSH). Secretion of these pituitary hormones is largely regulated by a negative-feedback loop by hypothalamic regulatory hormones and by signals that originate from the target site of pituitary action. Six hypothalamic hormones have been characterized: dopamine, the prolactin-inhibiting hormone; somatostatin, the GH release–inhibiting hormone; GH-releasing hormone; corticotropin-releasing hormone; gonadotropin-releasing hormone; and TRH. Most pituitary tumors (>60%) are hypersecretory and are classified according to the excess production of a specific anterior pituitary hormone.

The most common disorders of pituitary hypersecretion are those related to excesses of prolactin (amenorrhea, galactorrhea, and infertility), ACTH (Cushing syndrome), and GH (acromegaly). In addition to knowing the pathophysiologic processes of the disease involved, the anesthesiologist must determine whether the patient recently underwent air pneumoencephalography (almost obsolete, but still used rarely). If so, nitrous oxide should not be used to lessen the risk of intracranial hypertension from gas collection. CT or MRI of the sella has largely replaced neuroencephalography.

More than 99% of cases of acromegaly are attributable to pituitary adenoma (or use of recombinant human GH). Thus the primary treatment of acromegaly is transsphenoidal surgery (or withdrawal of drug) and symptomatic treatment of the carpal tunnel or other syndromes provoked. If the pituitary tumor is not totally removed, patients are often offered external pituitary irradiation. In the case of suprasellar extension, conventional transfrontal hypophysectomy is often performed. The dopaminergic agonist bromocriptine can lower GH levels, but the long-term follow-up with this drug is not favorable. Octreotide, a long-acting analogue of somatostatin, now given in depot form approximately once a month, produces effective palliation in 50% of patients. Other medical therapies such as pegvisomant or somatostatin analogues are also medications that have been tried before surgical intervention. In 2011, new guidelines were published with few changes to the available recommendations.[99] However, the new guidelines reported some evidence that medication taken preoperatively may result in a better postoperative outcome.

Difficulty with endotracheal intubation should be anticipated in a patient with acromegaly; lateral neck radiographs or CT scans of the neck and direct or indirect visualization can identify patients with subglottic stenosis or an enlarged tongue, mandible, epiglottis, or vocal cords. If placement of an arterial line is necessary, a brachial or femoral site may be preferable to a radial site.[100]

Anterior Pituitary Hypofunction

Anterior pituitary hypofunction results in deficiency of one or more of the following hormones: GH, TSH, ACTH, prolactin, or gonadotropin. No special preoperative and preprocedure preparation is required for a patient deficient in prolactin or gonadotropin; deficiency in GH, however, can result in atrophy of cardiac muscle, a condition that may necessitate preoperative and preprocedure cardiac evaluation. Nonetheless, anesthetic problems have not been documented in patients with isolated GH deficiency. Acute deficiencies are another matter.

Acute pituitary deficiency is often caused by bleeding into a pituitary tumor. In surgical specimens of resected adenomas, as many as 25% show evidence of hemorrhage. These patients often have acute headache, visual loss, nausea or vomiting, ocular palsy, disturbances of consciousness, fever, vertigo, or hemiparesis. In such patients, rapid transsphenoidal decompression should be accompanied by consideration of replacement therapy, including glucocorticoids and the treatment of increased intracranial pressure.

Obstetric anesthesiologists are often aware of these pituitary failure problems; Sheehan syndrome is the clinical manifestation of pituitary infarction associated with hypotension during or after obstetric hemorrhage. Conditions that strongly suggest this diagnosis are failure to start postpartum lactation, increasing fatigue, cold intolerance, and especially hypotension unresponsive to volume replacement and pressors; treatment is prompt hormone therapy.[100a]

Posterior Pituitary Hormone Excess and Deficiency

Secretion of vasopressin or antidiuretic hormone (ADH) is enhanced by increased serum osmolality or the presence of hypotension. Inappropriate secretion of vasopressin, without relation to serum osmolality, results in hyponatremia and fluid retention. This inappropriate secretion can result from the following: a variety of CNS lesions; drugs including nicotine, narcotics, tramadol, chlorpropamide, clofibrate, vincristine, vinblastine, and cyclophosphamide; and pulmonary infections, hypothyroidism, adrenal insufficiency, and ectopic production from tumors. Preoperative and preprocedure management of a surgical patient with inappropriate secretion of vasopressin includes appropriate treatment of the causative disorders and restriction of water. Occasionally, drugs that inhibit the renal response to ADH (e.g., lithium or demeclocycline) should be administered preoperatively to restore normal intravascular volume and electrolyte status.

Most of the clinical features associated with the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) are related to hyponatremia and the resulting brain edema; such features include weight gain, weakness, lethargy, mental confusion, obtundation, and disordered reflexes and may culminate in convulsions and coma.

Investigators have recognized that up to 20% of long-distance runners have SIADH with increased vasopressin secretion. Because such people infrequently undergo surgical treatment of injuries, SIADH symptoms and laboratory evaluation may be routine for that group as well.

SIADH should be suspected in any patient with hyponatremia who excretes urine that is hypertonic relative to plasma. The following laboratory findings further support the diagnosis:

1. Urinary sodium greater than 20 mEq/L
2. Low serum levels of BUN, creatinine, uric acid, and albumin
3. Serum sodium lower than 130 mEq/L
4. Plasma osmolality lower than 270 mOsm/L
5. Urine hypertonic relative to plasma

Noting the response to water loading is a useful way of evaluating patients with hyponatremia. Patients with SIADH are unable to excrete dilute urine even after water loading. Assay of ADH in blood can confirm the diagnosis. Too vigorous treatment of chronic hyponatremia can result in disabling osmotic demyelination syndrome.[101,102] The increase in serum sodium should not be greater than 1 mEq/L/h.[101,102]

Patients with mild to moderate symptoms of water intoxication can be treated with restriction of fluid intake to approximately 500 to 1000 mL/day. Patients with severe water intoxication and CNS symptoms may need vigorous treatment consisting of intravenous administration of hypertonic saline solutions until symptoms resolve, followed by fluid restriction.

Treatment should be directed at the underlying problem. If SIADH is drug induced, use of the drug should be withdrawn. Inflammation should be treated with appropriate measures, and neoplasms should be managed by surgical resection, irradiation, or chemotherapy, whichever is indicated.

No drugs are available that can suppress release of ADH from the neurohypophysis or from a tumor. Phenytoin (Dilantin) and narcotic antagonists such as naloxone and butorphanol have some inhibiting effect on physiologic ADH release but are clinically ineffective in patients with SIADH. Drugs that block the effect of ADH on renal tubules include lithium, which is rarely used because its toxicity often outweighs its benefits, and demethylchlortetracycline in doses of 900 to 1200 mg/day. Demethylchlortetracycline interferes with the ability of the renal tubules to concentrate urine, thereby causing excretion of isotonic or hypotonic urine and lessening the hyponatremia. This drug can be used in ambulatory patients with SIADH when it is difficult to restrict fluids.

When a patient with SIADH comes to the operating room for any surgical procedure, fluids are managed by measuring volume status, when the clinical picture is unclear the use of arterial wave form analysis, central venous pressure, pulmonary artery pressure, or transthoracic and/or transesophageal echocardiography may be of value. Despite the common impression that SIADH is frequently seen in older patients in the postoperative period, studies have shown that the patient's age and the type of anesthetic used have no bearing on the postoperative development of SIADH. It is common to see several patients in the neurosurgical ICU suffering from this syndrome. The diagnosis is usually one of exclusion. Patients with SIADH generally require only restriction of intravenous fluids, very rarely is hypertonic saline needed.

Lack of ADH, which results in diabetes insipidus, is caused by pituitary disease, brain tumors, infiltrative diseases such as sarcoidosis, head trauma (including trauma after neurosurgery), or lack of a renal response to ADH. The last can result from such diverse conditions as hypokalemia, hypercalcemia, sickle cell anemia, obstructive uropathy, and renal insufficiency. Preoperative or preprocedure treatment of diabetes insipidus consists of restoring normal intravascular volume by replacing urinary losses, administering desmopressin acetate (DDAVP) nasally, and giving daily fluid requirements intravenously.

Perioperative management of patients with diabetes insipidus is based on the extent of the ADH deficiency. Management of a patient with complete diabetes insipidus and a total lack of ADH does not usually present any major problem as long as the side effects of the drug are avoided and the presence of the condition is known preoperatively. Just before the surgical procedure, the patient is given the usual dose of DDAVP intranasally or an intravenous bolus of 100 milliunits of aqueous vasopressin, followed by a constant infusion of 100 to 200 milliunits/h.[1] The dose is usually adjusted to permit the daily breakthrough polyuria that prevents the iatrogenic syndrome of SIADH. All the intravenous fluids given intraoperatively should be isotonic to reduce the risk of water depletion and hypernatremia. Plasma osmolality should be frequently measured, both intraoperatively and immediately postoperatively. If plasma osmolality rises much higher than 300 mOsm/L, hypotonic fluids can be administered; the rate of the intraoperative vasopressin infusion can be increased to greater than 200 milliunits/h.

For patients who have a partial deficiency of ADH, it is not necessary to use aqueous vasopressin perioperatively unless plasma osmolality rises to more than 300 mOsm/L. Nonosmotic stimuli (e.g., volume depletion) and the stress of surgery usually cause the release of large quantities of ADH perioperatively. Consequently, these patients require only frequent monitoring of plasma osmolality during this period.

Because of side effects, the dose of vasopressin should be limited to that necessary for control of diuresis. The oxytocic and coronary artery–constricting properties of vasopressin make this limit especially applicable to patients who are pregnant or have CAD.

Diseases Involving the Cardiovascular System

HYPERTENSION

Analysis of the perioperative treatment of hypertension is important because of the prevalence of the condition (33.5% of adults aged 20 and over in the United States), the great risk in perioperative care of a hypertensive patient, and the high cost of unnecessary delays in surgical treatment. Numerous studies over the years have evaluated the impact of hypertension as one of the risk factors for cardiac morbidity. However, the need to delay surgery because of poorly controlled hypertension has been questioned. Weksler and colleagues studied 989 hypertensive patients who were treated on a long-term basis and who underwent noncardiac surgery with diastolic blood pressure between 110 and 130 mm Hg and no previous MI, unstable or severe angina pectoris, renal failure, pregnancy-induced hypertension, left ventricular hypertrophy, previous coronary revascularization, aortic stenosis, preoperative dysrhythmias, conduction defects, or stroke.[103] The control group had their surgical procedures postponed and remained in the hospital for control of blood pressure, and the study patients received 10 mg of nifedipine intranasally. No statistically significant differences in postoperative complications were observed, thus suggesting that this subset of patients without significant cardiovascular comorbid conditions can proceed with surgery despite elevated blood pressure on the day of the operation.

Several studies have assessed the relationship between cardiovascular disease and preoperative hypertension. In a multicenter study of patients undergoing coronary artery bypass graft (CABG), the presence of isolated systolic hypertension was associated with a 30% increased incidence of perioperative cardiovascular complications when compared with normotensive individuals.[104] Kheterpal and colleagues integrated data from their anesthesia information system (AIMS) and the American College of Surgeons National Surgical Quality Improvement Project (NSQIP) and found hypertension to be one of the independent predictors of events.[105] Wax and colleagues used AIMS to identify independent predictors of troponin elevation or death, and independent predictors of adverse outcome included increased baseline systolic blood pressure (SBP), intraoperative diastolic blood pressure lower than 85 mm Hg, increased intraoperative heart rate, blood transfusion, and anesthetic technique, controlling for standard risk factors.[106] A delay of surgery did not result in interval normalization of blood pressure.

Although preoperative blood pressure (both systolic and diastolic) is a significant predictor of postoperative morbidity, no data definitively establish whether preoperative treatment of hypertension reduces perioperative risk. Until a definitive study is performed, we recommend letting the weight of evidence guide preoperative treatment of a patient with hypertension. Such treatment would be based on three general beliefs: (1) the patient should be educated regarding the importance of lifelong treatment of hypertension, even isolated systolic hypertension; (2) perioperative hemodynamic fluctuations occur less frequently in treated than in untreated hypertensive patients (as demonstrated by Prys-Roberts and colleagues[107] and confirmed by Goldman and Caldera[108] and Mangano and associates[109]); and (3) hemodynamic fluctuations have some relation to morbidity. Kheterpal and colleagues demonstrated that patients who sustained a cardiac adverse event were more likely to experience an episode of mean arterial pressure lower than 50 mm Hg, an episode of 40% decrease in mean arterial pressure, and an episode of heart rate higher than 100 beats/min.[105] The data of Pasternack and colleagues and Weksler and associates imply that rapid correction of blood pressure or prevention of increases in heart rate may be all that is needed.[103,110] Sessler and colleagues (2018) studied 9765 patients in the POISE-II trial to assess the relationship between perioperative hypotension and a composite of MI and death within 30-days of surgery.[110aa] Intraoperatively, the estimated average relative effect was 1.08 (98.3% confidence interval [CI], 1.03, 1.12; $P < .001$) per 10-minute increase in hypotension duration. The average relative effect odds ratio was 2.83 (98.3% CI, 1.26, 6.35; $P = .002$) in patients with hypotension during the subsequent 4 days of hospitalization. The Intraoperative Norepinephrine to Control Arterial Pressure (INPRESS) study was a multicenter, randomized, parallel-group clinical trial in adult patients ($n = 298$) at increased risk of postoperative complications of individualized management strategy aimed at achieving a SBP within 10% of the reference value (i.e., patient's resting SBP) or standard management strategy of treating SBP less than 80 mm Hg or lower than 40% from the reference value during and for 4 hours following surgery.[110a] Management targeting an individualized SBP, compared with standard management, reduced the risk of postoperative organ dysfunction. Taken together, these data suggest that maintenance of normal blood pressure is critical in patients with hypertension.

The INPRESS study demonstrated that preoperative data should be used to determine the individualized range of suitable arterial blood pressure values that are tolerable by a particular patient during and after a surgical procedure. Importantly, hypotension in patients at risk for a cerebrovascular event should be avoided. For example, the POISE (Perioperative Ischemic Evaluation) study demonstrated that short-term β-blocker administration resulted in an increased incidence of stroke and death that was associated with an increased rate of hypotension.[111]

Preoperative Administration of All Antihypertensive Drugs

Continuation of all antihypertensive drugs preoperatively should be considered, except ACE inhibitors or angiotensin II antagonists, for which no clear consensus exists. Coriat and colleagues found that ACE inhibitors were associated with hypotension in 100% of patients during induction versus approximately 20% in whom ACE inhibitors were withheld on the morning of the surgical procedure.[112] Bertrand and coworkers performed a prospective randomized study that demonstrated that more severe hypotensive episodes requiring vasoconstrictor treatment occurred after induction of general anesthesia in patients treated on a long-term basis with an angiotensin II antagonist and receiving the drug on the morning before the operation than in those in whom angiotensin II antagonists were discontinued on the day before the surgical procedure.[113] Kheterpal and colleagues performed a propensity-matched analysis of 12,381 noncardiac surgical cases.[114] Patients with long-term ACE inhibitor or angiotensin receptor blocker (ARB) and diuretic therapy showed more periods with a mean arterial blood pressure lower than 70 mm Hg, periods with a 40% decrease in SBP, periods with a 50% decrease in SBP, and vasopressor boluses than did patients receiving diuretic therapy alone. If these drugs are continued, vasopressin is the drug of choice for refractory hypotension. Investigators at the Cleveland Clinic evaluated 79,228 patients (9905 ACE inhibitor users [13%] and 66,620 [87%] non–ACE inhibitor users) who had noncardiac surgery between 2005 and 2009.[115] These investigators did not find any association between use of ACE inhibitors and intraoperative or postoperative upper airway complications. ACE inhibitor use was not associated with in-hospital complications or increased 30-day mortality. Investigators of the VISION trial studied the relationship between withholding ACE inhibitors/angiotensin II receptor blockers and a primary composite outcome of all-cause death, stroke, or myocardial injury after noncardiac surgery at 30 days. Withholding ACE inhibitors/angiotensin II receptor blockers before major noncardiac surgery was associated with a lower risk of death and postoperative vascular events (150/1245 [12.0%] vs. 459/3557 [12.9%]; adjusted relative risk, 0.82; 95% CI, 0.70-0.96). In an accompanying editorial, London suggested that the current study does provide strong impetus for a randomized trial but does not warrant changes in local practice until such a trial is completed.[116]

ISCHEMIC HEART DISEASE

Preoperative evaluation of a patient with ischemic heart disease and a discussion of the AHA/ACC guidelines can be found in Chapters 31 and 54.[117] New guidelines were published in 2014 by both the AHA/ACC and the European

Society of Cardiology as well as the Canadian Cardiovascular Society in 2017.[118] This chapter will focus on the AHA/ACC guideline approach.[119,120]

Role of Coronary Artery Bypass Graft or Percutaneous Coronary Interventions Before Noncardiac Surgical Procedures

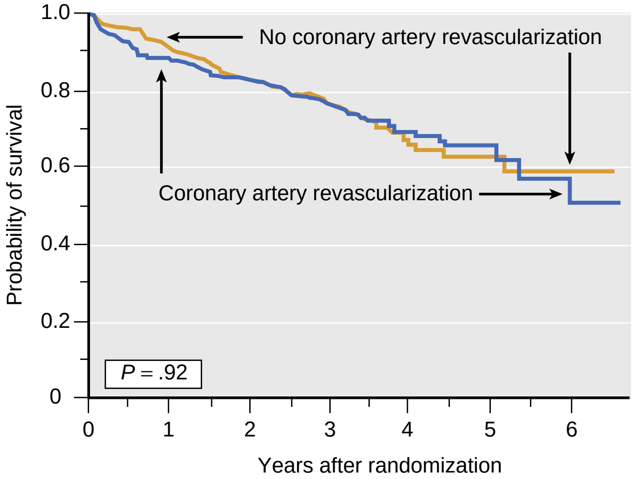
Coronary revascularization may reduce the perioperative risk before noncardiac surgery, but the evidence suggests that it is limited to those with indications similar to the nonsurgical arena. The strongest retrospective evidence comes from the Coronary Artery Surgery Study registry, which enrolled patients from 1978 to 1981. Operative mortality in patients with CABG performed before noncardiac surgery was 0.9% but was significantly higher at 2.4% in patients without previous CABG. However, a 1.4% mortality rate was associated with the CABG procedure itself.

The benefit of percutaneous coronary intervention (PCI) before noncardiac surgery has also been examined in several cohort studies. Posner and colleagues used an administrative dataset of patients who underwent PCI and noncardiac surgery in Washington State.[121] These investigators matched patients with coronary disease who were undergoing noncardiac surgery with and without previous PCI and looked at cardiac complications. In this nonrandomized design, Posner and colleagues noted a significantly lower rate of 30-day cardiac complications in patients who underwent PCI at least 90 days before the noncardiac surgery. However, PCI within 90 days of noncardiac surgery did not improve outcome. Although the explanation for these results is unknown, they may support the notion that PCI performed “to get the patient through surgery” may not improve perioperative outcome because cardiac complications may not occur in patients with stable or asymptomatic coronary stenosis. PCI may actually destabilize coronary plaque, which becomes manifest in the days or weeks after noncardiac surgery.

Godet and associates studied a cohort of 1152 patients after abdominal aortic surgery in which 78 patients underwent PCI.[122] In the PCI group, the observed percentages of patients with a severe postoperative coronary event (9.0%; 95% CI, 4.4-17.4) or death (5.1% [95% CI, 2.0-12.5]) were not significantly different from the expected percentages (8.2% and 6.9%, respectively), which was confirmed by propensity analysis. PCI did not seem to significantly limit cardiac risk or death after aortic surgery.

Several randomized trials have addressed the value of testing and CABG or PCI, or both, in a subset of patients. McFalls and colleagues reported the results of a multicenter randomized trial in the VA Health System in which patients with documented CAD on coronary angiography, excluding those with left main CAD or a severely depressed ejection fraction (<20%), were randomized to CABG (59%), or percutaneous transluminal coronary angioplasty (PTCA; 41%) versus routine medical therapy.[123] At 2.7 years after randomization, mortality in the revascularization group was not significantly different (22%) from that in the no-revascularization group (23%; Fig. 32.4). Within 30 days after the vascular operation, postoperative MI, defined by elevated troponin levels, occurred in 12% of the revascularization group and in 14% of the no-revascularization group (P = .37). The authors suggested that coronary revascularization is not indicated in patients with stable CAD, and their results further support the lack of efficacy of PCI or CABG for single- or double-vessel disease before noncardiac surgery. However, in a follow-up analysis, Ward and coauthors reported improved outcome in the subset of patients who underwent CABG versus PCI.[124]

Poldermans and colleagues randomized 770 patients about to undergo major vascular surgery and considered to have intermediate cardiac risk, defined as the presence of 1 or 2 cardiac risk factors, to either undergo further risk stratification with stress imaging or proceed directly to surgery.[125] All patients received bisoprolol with a targeted heart rate of 60 to 65 beats/min initiated before and continued after the surgical procedure. The 30-day incidence of cardiac death and nonfatal MI was similar in both groups (1.8% in the no-testing group vs. 2.3% in the tested group). The conclusions of the authors were that further risk stratification in this group of patients considered to be at intermediate risk based on clinical history alone was unnecessary as long as perioperative β-blockers were used and that testing only delayed necessary vascular surgery. In a pilot study, Poldermans and associates tested patients with more than three risk factors; 101 (23%) showed extensive ischemia and were randomly assigned to revascularization (n = 49) or no revascularization.[126] Revascularization did not improve 30-day outcome; the incidence of the composite end-point was 43% versus 33% (odds ratio [OR], 1.4; 95% CI, 0.7-2.8; P = .30). In addition, no benefit during 1-year follow-up was observed after coronary revascularization (49% vs. 44%; OR, 1.2; 95% CI, 0.7-2.3; P = .48). Concern was expressed by Erasmus University (Rotterdam, the Netherlands) regarding the scientific integrity of studies led by Poldermans, as detailed in Erasmus MC Follow-up Investigation Committee: *Report on the 2012 follow-up investigation of possible breaches of academic integrity, September 30, 2012* (https://www.forbes.com/sites/larryhusten/2012/10/09/erasmus-medical-center-releases-final-report-on-cardiovascular-research-scandal/#675d592528ae). The articles have



Years	**1**	**2**	**3**	**4**	**5**	**6**
No. at risk						
Revascularization	226	175	113	65	18	7
No revascularization	229	172	108	55	17	12

Fig. 32.4 Long-term survival in patients randomized to coronary revascularization or routine care in patients with coronary artery disease on angiography and undergoing major vascular surgical procedures in the Coronary Artery Revascularization Prophylaxis trial. (From McFalls EO, Ward HB, Moritz TE, et al. Coronary-artery revascularization before elective major vascular surgery. *N Engl J Med.* 2004;351:2795–2804.)

not been retracted, but these data should be viewed with some skepticism. The authors of the 2014 AHA/ACCF Guidelines decided that the nonretracted decrease publications and/or other derivative studies by Poldermans that are relevant to the topic can only be cited in the text with a comment about the finding compared with the current recommendation but did not form the basis of that recommendation.

One issue in interpreting the results is that the length of time between coronary revascularization and noncardiac surgery most likely has an impact on its protective effect and potential risks. Back and coworkers studied 425 consecutive patients undergoing 481 elective major vascular operations at an academic VA Medical Center.[127] Coronary revascularization was classified as recent (CABG < 1 year; PTCA < 6 months) in 35 cases (7%), prior (CABG >1 year and ≤5 years; PTCA >6 months and ≤2 years) in 45 cases (9%), and remote (CABG ≥ 5 years; PTCA ≥ 2 years) in 48 cases (10%). Outcomes in patients with previous PTCA were similar to those after CABG ($P = .7$). Significant differences in adverse cardiac events and mortality were found among patients with CABG performed within 5 years or PTCA within 2 years (6.3%, 1.3%, respectively), individuals with remote revascularization (10.4%, 6.3%), and nonrevascularized patients stratified at high risk (13.3%, 3.3%) or intermediate/low risk (2.8%, 0.9%). The authors concluded that previous coronary revascularization (CABG < 5 years; PTCA < 2 years) may provide only modest protection against adverse cardiac events and mortality after major arterial reconstruction.

PCI using coronary stenting poses several special issues. Kaluza and associates reported on the outcome of 40 patients who underwent prophylactic coronary stent placement less than 6 weeks before major noncardiac surgery requiring general anesthesia.[128] Among these patients, 7 MIs, 11 major bleeding episodes, and 8 deaths were noted. All deaths and MIs, as well as 8 of the 11 bleeding episodes, occurred in patients subjected to surgical procedures less than 14 days after stenting. Four patients died after undergoing surgical procedures 1 day after stenting. Wilson and colleagues reported on 207 patients who underwent noncardiac surgery within 2 months of stent placement.[129] Eight patients died or suffered an MI, all of whom were among the 168 patients who had surgical procedures 6 weeks after stent placement. Vicenzi and coworkers studied 103 patients and reported that the risk of suffering a perioperative cardiac event was 2.11-fold greater in patients with recent stents (<35 days before surgery) than in those who underwent PCI more than 90 days before surgical procedures.[130] Leibowitz and associates studied a total of 216 consecutive patients who underwent PCI within 3 months of noncardiac surgery (PTCA, 122; stent, 94).[131] A total of 26 patients (12%) died, 13 in the stent group (14%), and 13 in the PTCA group (11%), a nonsignificant difference. The incidence of acute MI and death within 6 months was not significantly different (7% and 14% in the stent group and 6% and 11% in the PTCA group, respectively). Significantly more events occurred in the two groups when noncardiac surgery was performed within 2 weeks of PCI. Based on the accumulating data, elective noncardiac surgery after PCI, with or without stent placement, should be delayed for 4 to 6 weeks.

Drug-eluting stents may represent an even greater problem during the perioperative period based on case reports. Nasser and coauthors described two patients with in-stent thrombosis occurring 4 and 21 months after the implantation of sirolimus-eluting stents.[132] Drug-eluting stents may represent an additional risk over a prolonged period (≤12 months), particularly if antiplatelet drugs are discontinued.[133] One study demonstrated that although the frequency of major noncardiac surgery in the year after drug-eluting stent placement was more than 4%, the overall risk of adverse outcomes was less than previously reported when surgical procedures were performed months after drug-eluting stent placement.[134] However, the risk was significantly increased in the week after major noncardiac surgery. A population-based study in Canada using administrative healthcare databases demonstrated that the earliest optimal time for elective surgery is 46 to 180 days after bare-metal stent implantation or more than 180 days after drug-eluting stent implantation.[135] Hawn and colleagues used a national, retrospective cohort study of 41,989 VA and non-VA operations occurring in the 24 months after coronary stent implantation between 2000 and 2010.[136] Among patients undergoing noncardiac surgery within 2 years of coronary stent placement, major adverse cardiac events were associated with emergency surgery and advanced cardiac disease but not stent type or timing of surgery beyond 6 months after stent implantation. The 2016 DAPT Guidelines (Fig. 32.5) suggest continuing aspirin therapy in all patients with a coronary stent and discontinuing clopidogrel for as short a time interval as possible for patients with bare-metal stents less than 30 days or drug-eluting stents less than 6 months; with DAPT it can be discontinued.[136a]

Based upon the non-perioperative literature, there is a suggestion that holding clopidogrel for the traditional 8 days may actually increase risk associated with a hypercoagulable rebound suggesting a shorter period of time may be optimal. A recent cohort study suggests that withdrawal of antiplatelet agents greater than 5 days is associated with increased major adverse cardiac events.[136b]

Perioperative Risk Factors for Cardiac Morbidity and Mortality

A thorough history should focus on cardiovascular risk factors and symptoms or signs of unstable cardiac disease states, such as myocardial ischemia with minimal exertion, active CHF, symptomatic valvular heart disease, and significant cardiac arrhythmias. The presence of unstable angina is associated with a 28% incidence of perioperative MI.[137] Such patients would benefit from delaying elective surgery to address their CAD. For those patients with chronic stable angina, exercise tolerance appears to be a good method of assessing perioperative risk.

In virtually all studies, the presence of active CHF has been associated with increased perioperative cardiac morbidity.[138] In addition, multiple studies have demonstrated that reduced ejection fraction is associated with an increased incidence of perioperative cardiac events.[139,140] Flu and colleagues performed echocardiography in patients undergoing vascular surgery and found that for open surgical procedures, asymptomatic systolic left ventricular dysfunction and asymptomatic diastolic left ventricular

Proceed with surgery

Fig. 32.5 Proposed algorithm for antiplatelet management in patients with percutaneous coronary intervention and noncardiac surgery. *ASA,* Aspirin; *BMS,* bare metal stent; *DAPT,* dual antiplatelet therapy; *DES,* drug-eluting stent. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guidelines on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines. *J Am Coll Cardiol.* 2014;64:e77–e137.)

dysfunction were both associated with increased 30-day cardiovascular event rates (OR, 2.3; 95% CI, 1.4-3.6; and OR, 1.8; 95% CI 1.1 to 2.9, respectively) and long-term cardiovascular mortality (hazard ratio, 4.6; 95% CI 2.4-8.5; and hazard ratio, 3.0; 95% CI 1.5 to 6.0, respectively).[141] In patients undergoing endovascular surgery ($n = 356$), only symptomatic heart failure was associated with an increase in 30-day cardiovascular events and long-term cardiovascular mortality. These results suggest that stabilization of ventricular function and treatment of pulmonary congestion is prudent before elective surgery.

A recent MI has traditionally been an important predictor of perioperative risk. The more recent the MI, particularly within 3 to 6 months, the greater is the perioperative risk. However, like the Goldman Cardiac Risk Index, medicine has changed and outcomes are improved. The 2014 AHA/ACC Foundation (AHA/ACCF) guidelines advocate the use of 60 days as being high risk.[119] After that time, further risk stratification depends on clinical symptoms.

For those patients without overt symptoms or a history of CAD, the probability of CAD varies with the type and number of atherosclerotic risk factors present. Diabetes accelerates the progression of atherosclerosis, which can frequently be silent, leading many clinicians to assume that diabetes is a CAD equivalent and treating patients as such. Diabetes is an independent risk factor for perioperative cardiac morbidity, and the preoperative treatment with insulin has been included in the Revised Cardiac Risk Index (RCRI). In attempting to determine the degree of the increased risk associated with diabetes, the treatment modality, duration of the disease, and other associated end-organ dysfunction should be taken into account.

Significant intraoperative factors that correlate with perioperative risk and that may be avoided or altered are (1) unnecessary use of vasopressors,[142,143] (2) unintentional hypotension[144-146] (this point is controversial, however, because some investigators have found that unintentional hypotension does not correlate with perioperative morbidity[143]), (3) hypothermia,[147] (4) too low or too high a hematocrit,[148,149] and (5) lengthy operations.[145]

Significant intraoperative factors that correlate with perioperative morbidity and probably cannot be avoided are (1) emergency surgery and (2) thoracic or intraperitoneal surgery or above-the-knee amputations.[145,150-164]

Several risk indices were developed in a prospective cohort study by Lee and associates.[164] They studied 4315 patients 50 years old or older who were undergoing elective major noncardiac procedures in a tertiary care teaching hospital. The six independent predictors of complications included in a RCRI were high-risk type of surgery, history of ischemic heart disease, history of CHF, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine greater than 2.0 mg/dL; increasing cardiac complication rates were noted with an increasing number of risk factors.[164] The RCRI has become the standard tool in the literature for assessing perioperative cardiac risk in a given individual and has been used to direct the decision to perform cardiovascular testing and implement perioperative management protocols. It has been validated for both short-term and long-term cardiovascular outcomes.[165] It has also been shown to predict long-term quality of life.[165] Therefore, the RCRI can be used to help define both the short-term and long-term risks of cardiovascular disease in the surgical patient.

The American College of Surgeons NSQIP created a Surgical Risk Calculator from 525 participating hospitals and more than 1 million operations.[166] This risk calculator uses the specific current procedural terminology code of the procedure being performed to enable procedure-specific risk assessment and includes 21 patient-specific variables (e.g., age, sex, body mass index, dyspnea, previous MI). From this input, it calculates the percentage of risk of a major adverse cardiac event, death, and eight other outcomes. Use of this risk calculator may offer the best estimation for surgery-specific risk of a major adverse cardiac event and death.

The American College of Surgeons NSQIP Myocardial Infarction and Cardiac Arrest risk prediction rule is more specific for cardiac complications.[167] Using these definitions of outcome and chart-based data collection methods, the authors derived a risk index that was robust in the derivation and validation stages and appeared to outperform the RCRI (which was tested in the same dataset) in terms of discriminative power, particularly among patients undergoing vascular surgery.

A primary issue with all these indices is that a simple estimate of risk does not help in refining perioperative management for an individual patient. Therefore, the consultant must communicate the extent and stability of the patient's CAD, rather than make a simple statement of risk classification.

The goal in providing anesthesia to patients with ischemic heart disease is to achieve the best preoperative condition obtainable by treating conditions that correlate with perioperative risk. The next step is to intraoperatively monitor for conditions that correlate with perioperative risk and avoid circumstances that lead to perioperative risk.

Preoperative and Preprocedure Therapy

The only way known to increase oxygen supply to the myocardium of patients with coronary artery stenosis is to maintain adequate diastolic blood pressure, hemoglobin concentration, and oxygen saturation. The main goals of anesthesia practice for these patients have been to decrease the determinants of myocardial oxygen demand, heart rate, ventricular wall tension, and contractile performance, and to improve plaque stabilization. Thus medical management designed to preserve all viable myocardial tissue may include the following:

1. Multiple studies have demonstrated improved outcome in patients given perioperative β-blockers, especially if heart rate is controlled, acknowledging the previously discussed concerns regarding the quality of the studies from the Erasmus group.[167a,b] Subsequent studies demonstrated that β-blockers may not be effective if heart rate is not well controlled, or in lower risk patients.[167c-e] The POISE trial was published in which 8351 high-risk β-blocker-naïve patients were randomized to high-dose continuous-release metoprolol versus placebo.[167f]
2. There was a significant reduction in the primary outcome of cardiovascular events associated with a 30% reduction in MI rate, but with a significantly increased rate of 30-day all-cause mortality and stroke. Several recent cohort studies continue to support the fact that high-risk patients on β-blockers were associated with improved outcome. A Canadian administrative dataset suggested that the perioperative morbidity would be higher if β-blockers were started within 7 days as compared to 8 days or greater. As part of the update to the current ACC/AHA Guidelines, an Evidence Review Committee was formed to independently review the data on perioperative β-blockade. Perioperative β-blockade started within 1 day or less before noncardiac surgery prevents nonfatal MI but increases risks of stroke, death, hypotension, and bradycardia.[167g] Without the controversial DECREASE studies, there are insufficient data on β-blockade started two or more days prior to surgery. Wallace and associates reported that perioperative β-blockade administered according to the Perioperative Cardiac Risk Reduction protocol is associated with a reduction in 30-day and 1-year mortality.[167h] Perioperative withdrawal of β-blockers is associated with increased mortality. The current ACCF/AHA Guidelines on perioperative β-blockade advocate that perioperative β-blockade is a Class I indication and should be used in patients previously on β-blockers. The new recommendations changed the recommendation from a Class IIa to IIb for patients undergoing vascular surgery who are at high cardiac risk owing to CAD or the finding of cardiac ischemia on preoperative testing (Box 32.3).
2. Vasodilation (with nitroglycerin or its “long-acting” analogues nitroprusside, hydralazine, or prazosin) to decrease ventricular wall tension may be beneficial, although currently no randomized trials support the prophylactic use of these agents.[109,110,168] There are no data to support the routine use of pulmonary artery catheters and transesophageal echocardiography for this type of patient.[158,169] The intraoperative management of patients with ischemic heart disease is discussed in further detail in Chapters 31 and 54 and in published guidelines.[117]
3. Other medications. In POISE II, α-2 agonists were not shown to improve perioperative outcome.[169a] POISE II also evaluated the effectiveness of aspirin therapy in a cohort of patients without a recent stent. Administration of aspirin before surgery and throughout the early postsurgical period had no significant effect on the rate of a composite of death or nonfatal MI but increased the risk of major bleeding.[169b] Most recently, perioperative statins have been shown to improve cardiac outcome. Durazzo and colleagues published a randomized trial of 200 vascular surgery patients in which statins were started an average of 30 days prior to vascular surgery.[169c] A significant reduction in cardiovascular complications was demonstrated using this protocol. Le Manach and colleagues demonstrated that statin

BOX 32.3 2014 ACC/AHA Recommendations for Perioperative β-Blockade

Class I

- β-Blockers should be continued in patients undergoing surgery who have been on β-blockers chronically.[111-117] **(Level of Evidence: B)**

Class IIa

- It is reasonable for the management of β-blockers after surgery to be guided by clinical circumstances, independent of when the agent was started.[110,117,118] **(Level of Evidence: B)**

Class IIb

- In patients with intermediate- or high-risk myocardial ischemia noted in preoperative risk stratification tests, it may be reasonable to begin perioperative β-blockers.[119] **(Level of Evidence: C)**
- In patients with three or more RCRI risk factors (e.g., diabetes mellitus, heart failure, coronary artery disease, renal insufficiency, cerebrovascular accident), it may be reasonable to begin β-blockers before surgery.[117] **(Level of Evidence: B)**
- In patients with a compelling long-term indication for β-blocker therapy but no other RCRI risk factors, initiating β-blockers in the perioperative setting as an approach to reduce perioperative risk is of uncertain benefit.[111,117,120] **(Level of Evidence: B)**
- In patients in whom β-blocker therapy is initiated, it may be reasonable to begin perioperative β-blockers long enough in advance to assess safety and tolerability, preferably more than 1 day before surgery.[110,121-123] **(Level of Evidence: B)**

Class III: Harm

- β-Blocker therapy should not be started on the day of surgery.[110] **(Level of Evidence: B)**

RCRI, Revised cardiac risk index.

withdrawal greater than 4 days was associated with a 2.9 odds ratio of increased risk of cardiac morbidity in vascular surgery.[169d] The guidelines advocate continuing statin therapy in patients currently taking statins as a Class I indication. A multimodal approach to medical management should be taken in high-risk patients. There continues to be controversy regarding the optimal management of ACE inhibitors and ARBs. In the Veterans Administration, withholding ARB postoperatively is strongly associated with increased 30-day mortality, especially in younger patients, although residual confounding may be present.[169e] In the VISION trial, compared to patients who continued their ACE inhibitors/angiotensin II receptor blockers, the ACE/ARB users who withheld their agents in the 24 hours before surgery were less likely to suffer the primary composite outcome of all-cause death, stroke, or myocardial injury (adjusted relative risk, 0.82; 95% CI, 0.70 to 0.96; $P = .01$); and intraoperative hypotension (adjusted relative risk, 0.80; 95% CI, 0.72-0.93; $P < .001$).[169f] The current AHA/ACC Guidelines suggest that continuation of ACE inhibitors or angiotensin-receptor ARBs perioperatively is reasonable, but should be restarted as soon as reasonable. The new study questions this recommendation, but further randomized trials are needed.

4. Perioperative transfusion therapy is discussed in more detail in Chapter 49. The FOCUS (Functional Outcomes in Cardiovascular Patients Undergoing Surgical Repair of Hip Fracture) trial was unable to demonstrate benefit in high-risk patients with hip fracture between a high and low transfusion trigger.[170]

VALVULAR HEART DISEASE

Major alterations in the preoperative management of patients with valvular heart disease have been made regarding the use of anticoagulant therapy and are now based on the causes of the disease. Preoperative and intraoperative management of patients with valvular heart disease is discussed in Chapters 31 and 54.

The prognosis and the perioperative risk for patients with valvular heart disease depend on the stage of the disease. Although stenotic lesions typically progress faster than regurgitant lesions, regurgitant lesions from infective endocarditis, rupture of the chordae tendineae, or ischemic heart disease can be rapidly fatal. Left ventricular dysfunction is common in the late stage of valvular heart disease, both stenotic and regurgitant.

Preoperative maintenance of drug therapy can be crucial; for example, a patient with severe aortic stenosis can deteriorate rapidly with the onset of atrial fibrillation or flutter because the atrial contribution to left ventricular filling can be critical in maintaining cardiac output. One of the most serious complications of valvular heart surgery and of preoperative valvular heart disease is cardiac arrhythmia. Conduction disorders and long-term therapy with antiarrhythmic and inotropic drugs are discussed elsewhere in this chapter. The reader is referred to Chapter 78 and to other sources for discussion of the management of a child with congenital heart disease who is undergoing noncardiac surgery.[171]

Preoperative Antibiotic Prophylaxis for Endocarditis

Patients who have any form of valvular heart disease, as well as those with intracardiac (ventricular septal or atrial septal defects) or intravascular shunts, should be protected against endocarditis at the time of a known bacteremic event. Endocarditis has occurred in a sufficiently significant number of patients with hypertrophic cardiomyopathy (subvalvular aortic stenosis, asymmetric septal hypertrophy) and mitral valve prolapse to warrant the inclusion of these two conditions in the prophylaxis regimen.

Bacteremia occurs after the following events: dental extraction, 30% to 80%; brushing of teeth, 20% to 24%; use of oral irrigation devices, 20% to 24%; barium enema, 11%; transurethral resection of the prostate (TURP), 10% to 57%; upper GI endoscopy, 8%; nasotracheal intubation, 16% (4 of 25 patients); and orotracheal intubation, 0% (0 of 25 patients). The most recent guidelines from the AHA consisted of an update in 2008 from the AHA/ACC on endocarditis in patients with valvular heart disease, with changes from the 2006 document shown in Table 32.6.[172]

TABLE 32.6 Changes Related to Endocarditis Prophylaxis: American College of Cardiology/American Heart Association Guidelines on Valvular Heart Disease

2006 VHD Guideline Recommendations	2008 VHD Focused Update Recommendations	Comments
Class I	**Class IIa**	
Prophylaxis against infective endocarditis is recommended for the following patients: Patients with prosthetic heart valves and patients with a history of infective endocarditis *(level of evidence: C)* Patients who have complex cyanotic congenital heart disease (e.g., single-ventricle states, transposition of the great arteries, tetralogy of Fallot) *(level of evidence: C)* Patients with surgically constructed systemic pulmonary shunts or conduits *(level of evidence: C)* Patients with congenital cardiac valve malformations, particularly those with bicuspid aortic valves, and patients with acquired valvular dysfunction (e.g., rheumatic heart disease) *(level of evidence: C)* Patients who have undergone valve repair *(level of evidence: C)* Patients who have hypertrophic cardiomyopathy when there is latent or resting obstruction *(level of evidence: C)* Patients with MVP and auscultatory evidence of valvular regurgitation and/or thickened leaflets on echocardiography* *(level of evidence: C)*	Prophylaxis against infective endocarditis is reasonable for the following patients at highest risk for adverse outcomes from infective endocarditis who undergo dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa: Patients with prosthetic cardiac valves or prosthetic material used for cardiac valve repair *(level of evidence: B)* Patients with previous infective endocarditis *(level of evidence: B)* Patients with CHD *(level of evidence: B)* Unrepaired cyanotic CHD, including palliative shunts and conduits *(level of evidence: B)* Completely repaired congenital heart defect repaired with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure *(level of evidence: B)* Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (both of which inhibit endothelialization) *(level of evidence: B)* Cardiac transplant recipients with valve regurgitation as a result of a structurally abnormal valve *(level of evidence: C)*	Modified recommendation (changed class of recommendation from I to IIa, changed text); no class I recommendations exist for infective endocarditis prophylaxis

CHD, Congenital heart disease; *MVP,* mitral valve prolapse; *VHD,* valvular heart disease.

Cardiac Valve Prostheses and Anticoagulant Therapy and Prophylaxis for Deep Vein Thrombosis

In patients with prosthetic valves, the risk of increased bleeding during a procedure in a patient receiving antithrombotic therapy must be weighed against the increased risk of thromboembolism caused by stopping the therapy. Common practice in patients undergoing noncardiac surgery with a mechanical prosthetic valve in place is cessation of anticoagulant therapy 3 days preoperatively. This time frame allows the international normalized ratio to fall to less than 1.5 times normal. The oral anticoagulants can then be resumed on postoperative day 1. Using a similar protocol, Katholi and colleagues found no perioperative episodes of thromboembolism or hemorrhage in 25 patients.[173] An alternative approach in patients at high risk for thromboembolism is conversion to heparin during the perioperative period. The heparin can then be discontinued 4 to 6 hours preoperatively and resumed shortly thereafter. Current prosthetic valves may have a lower incidence of this complication, and the risk associated with heparin may outweigh its benefit in the perioperative setting. According to the AHA/ACC guidelines, heparin can usually be reserved for patients who have had a recent thrombus or embolus within 1 year, those with demonstrated thrombotic problems when previously off therapy, and those with more than three risk factors (atrial fibrillation, previous thromboembolism, hypercoagulable condition, and mechanical prosthesis).[174] A lower threshold for recommending heparin should be considered in patients with mechanical valves in the mitral position, in whom a single risk factor would be sufficient evidence of high risk. Subcutaneous low-molecular-weight heparin offers an alternative outpatient approach.[175] It is appropriate for the surgeon and cardiologist to discuss the optimal perioperative management for such a patient, including a review of the most recent guidelines.[176] A new guideline publication was published in 2014.[176a]

Regional anesthetic techniques may be avoided, although this issue is controversial as many practitioners will use regional anesthesia in patients who are receiving prophylaxis for deep vein thrombosis.[177-180] However, epidural hematoma has been associated with anticoagulant therapy in many reports. Large retrospective reviews of outcome after epidural or spinal anesthesia, or both, during or shortly before initiation of anticoagulant therapy with heparin have not reported neurologic dysfunction related to hematoma formation in any patient.[181,182] This paucity of damaging epidemiologic evidence, although reassuring, does not reduce the need for frequent evaluation of neurologic function and a search for back pain in the perioperative period after regional anesthesia in any patient receiving any anticoagulation or antiplatelet.[177,183-185] The risk of regional anesthesia concurrent with prophylaxis for deep vein thrombosis with heparin is greater with the use of low-molecular-weight heparin. Heparin-induced thrombocytopenia has been treated successfully with intravenous immunoglobulin.[179] The American Society of Regional

Anesthesia and Pain Management has issued a consensus statement on the use of regional anesthesia in anticoagulated patients.[186] They suggest that the decision to perform spinal or epidural anesthesia or analgesia, and the timing of catheter removal in a patient receiving antithrombotic therapy should be made on an individual basis, with the small but definite risk of spinal hematoma weighed against the benefits of regional anesthesia for a specific patient.

It was, previously, determined that venous thromboembolism is so common in postoperative patients that almost 1% of postsurgical patients die of fatal pulmonary embolism (Table 32.7).[187] More recently, it has been estimated that venous thromboembolism is responsible for up to 10% of all hospital-related deaths.[187a] Because of this high mortality risk, prophylaxis against deep vein thrombosis has attained widespread acceptance; thus prophylaxis begins with 5000 units of heparin given subcutaneously 2 hours preoperatively.[187-189] Other trials have shown equal effect with external pneumatic sequential compression devices.[188,190] The most current recommendations are available from the American College of Chest Physicians for prophylaxis against venous thromboembolism in 2012.[190a]

TABLE 32.7 Incidence of Deep Vein Thrombosis and Fatal Pulmonary Embolism

	INCIDENCE OF		
Type of Surgery	**Deep Vein Thrombosis (%)**	**Proximal Deep Vein Thrombosis (%)**	**Fatal Pulmonary Embolism (%)**

Other bed bound	26		

TURP, Transurethral resection of the prostate.

Another problem that can arise is managing a pregnant patient with a prosthetic valve during delivery. It is recommended that warfarin be replaced by subcutaneous heparin during the peripartum period. During labor and delivery, elective induction of labor is advocated with discontinuance of all anticoagulant therapy, as indicated for the particular valve prosthesis (discussed earlier).[191]

Auscultation of the prosthetic valve should be performed preoperatively to verify normal functioning. Abnormalities in such sounds warrant preoperative consultation and verification of functioning.

CARDIAC CONDUCTION DISTURBANCES: CARDIAC ARRHYTHMIAS

Bradyarrhythmias, especially if profound or associated with dizziness or syncope, are generally managed with pacemakers. However, chronic bifascicular block (right bundle branch block with a left anterior or posterior hemiblock or left bundle branch block with combined left anterior and posterior hemiblocks), even when only a first-degree heart block is present, can progress to complete heart block and sudden perioperative death on rare occasion. In six studies, less than 2% of the approximately 266 patients with bifascicular block progressed to complete heart block perioperatively.[192] Conversely, these patients have a high 5-year mortality rate (160 of 554 patients, or 29%). Most of the deaths were related to tachyarrhythmias or ischemic events not usually preventable by traditional pacemakers.[193] Thus the presence of a bifascicular block on the ECG should make the anesthesiologist worried about associated CAD or left ventricular dysfunction; an echocardiogram should be evaluated perioperatively. Nevertheless, these patients rarely have complete heart block perioperatively. Therefore, prophylactic preoperative insertion of temporary pacing wires for bifascicular block does not seem warranted; however, central access can be established in advance in the event that a temporary pacemaker needs to be inserted (most operating rooms do not rely on transthoracic pacing, although it may be attempted if available).[194] The actual pacemaker equipment and appropriate personnel should be immediately available, and the equipment should be tested regularly, because symptomatic heart block does occur perioperatively in more than 1% of patients. One study appears to have confirmed this rate of at least 1% for patients undergoing cardiac surgery.[195] One percent of patients in whom a pacing pulmonary artery catheter was not inserted preoperatively subsequently required pacing before cardiopulmonary bypass. By contrast, 19% of patients who had such a catheter in place underwent cardiac pacing before cardiopulmonary bypass. Predictors of the need for pacing included previous symptomatic bradyarrhythmia, a history of transient complete AV block, and aortic valve disease.

Older studies demonstrated that a rate of more than five PVCs per minute on preoperative examination correlates with perioperative cardiac morbidity.[144,151-153] To the classic criteria for treating PVCs (the presence of R-on-T couplets, the occurrence of more than three PVCs per minute, and multifocality of PVCs) must be added frequent (>10/h over a 24-hour period) and repetitive ventricular beats. Electrophysiologic and programmed ventricular stimulation studies are being used to indicate and guide treatment of patients with ischemic heart disease or recurrent arrhythmias and survivors of out-of-hospital cardiac arrest. Although such patients are often treated with antiarrhythmic therapy, attention to their underlying condition should be a focus of our preoperative management. Long-term antiarrhythmic therapy is discussed in the last section of this chapter, on drug therapy. Torsades de pointes is an arrhythmia characterized by episodes of alternating electrical polarity such that the major vector of the QRS complex seems to alternate around an isoelectric line. The hallmark enabling differential diagnosis from ventricular tachycardia is the unusual response of this arrhythmia to commonly used antiarrhythmic drugs. In other words, the use of drugs that prolong the QT interval (e.g., quinidine, procainamide, disopyramide, some of the antihistamines, and the antipsychotic phenothiazines) may well make the arrhythmia more frequent or of longer duration. Reports of the sudden occurrence of torsades de pointes during surgical procedures have been rare in the anesthesia literature. Immediate therapy consists of the administration of magnesium or electrical cardioversion, followed by overdrive cardiac pacing or the administration of β-adrenergic agonists and discontinuation of drugs that prolong the QT interval.

Premature atrial contractions and cardiac rhythms other than sinus also correlate with perioperative cardiac morbidity.[144,152] These arrhythmias may be more a marker of poor cardiovascular reserve than a specific cause of perioperative cardiac complications.

Preexcitation syndrome is the name for supraventricular tachycardias associated with AV bypass tracts.[196] Successful treatment, which is predicated on an understanding of the clinical and electrophysiologic manifestations of the syndrome, consists of either catheter ablation techniques or surgery using preoperative and intraoperative techniques that avoid release of sympathetic and other vasoactive substances and therefore tachyarrhythmias.[193,197,198] Anesthesia for electrophysiologic procedures is discussed in Chapter 55.

Disorders of the Respiratory and Immune Systems

GENERAL PREOPERATIVE AND PREPROCEDURE CONSIDERATIONS

Pulmonary complications after procedures requiring anesthesia are as common as cardiovascular complications—even more common if venous thromboembolism is included. It has, relatively recently, been estimated that postoperative respiratory complications can occur in up to 80% of surgical patients, noting obesity, preexisting pulmonary disease, and advanced age are among the chief risk factors.[198a] Thus pulmonary complications are equally as important or more important to the patient and the health system in terms of morbidity, mortality, length-of-stay extension, and cost. Today there is an even greater appreciation of the effects of smoking and sleep apnea on perioperative and long-term care has increased.[199-216] (Preoperative and preprocedure identification and perioperative care of patients with sleep apnea are discussed in the earlier section on obesity and in Chapter 58.)

The main purpose of preoperative testing is to identify patients at risk for perioperative complications so that appropriate perioperative therapy can be instituted to foster return to functional status. Preoperative assessment can also establish baseline function and the feasibility of surgical intervention. Whereas numerous investigators have used pulmonary function tests to define inoperability or high-risk versus low-risk groups for pulmonary complications, few have been able to demonstrate that the performance of any specific preoperative or intraoperative measure, except perhaps smoking cessation and physical activity such as a walking program, reliably decreases perioperative pulmonary morbidity or mortality and improves patient outcomes. Because routine preoperative pulmonary testing and care are discussed extensively in Chapter 41, the current discussion is limited to an assessment of the effectiveness of this type of care.

In fact, few randomized prospective studies indicate an outcome benefit of preoperative preparation. Stein and Cassara randomly allocated 48 patients to undergo preoperative therapy (cessation of smoking, administration of antibiotics for purulent sputum, and use of bronchodilating drugs, postural drainage, chest physiotherapy, and ultrasonic nebulizer) or no preoperative therapy.[212] The no-treatment group had a mortality of 16% and morbidity of 60%, as opposed to 0% and 20%, respectively, for the treatment group. In addition, the treatment group spent an average of 12 postoperative days in the hospital as compared with 24 days for the 21 survivors in the no-treatment group.[212]

Collins and colleagues prospectively examined the benefits of preoperative antibiotics, perioperative chest physiotherapy and therapy with bronchodilating drugs, and routine postoperative analgesia (morphine) on postoperative respiratory complications in patients with COPD.[217] Of these therapies, only preoperative treatment with antibiotics had a beneficial effect.

Hulzebos and colleagues performed a single-center randomized trial of intensive inspiratory muscle training.[218] Preoperative inspiratory muscle training reduced the incidence of postoperative pulmonary complications and the duration of postoperative hospitalization in patients at high risk of developing a pulmonary complication who were undergoing CABG surgery.

Warner and coworkers collected data retrospectively about smoking history and prospectively (concurrently) about pulmonary complications for 200 patients undergoing CABG.[219] These investigators documented that 8 weeks or more of smoking cessation was associated with a 66% reduction in postoperative pulmonary complications. Smokers who stopped for less than 8 weeks actually had an increase (from 33% for current smokers to 57.1% for recent quitters) in the rate of one or more of the six complications surveyed: purulent sputum with pyrexia; need for respiratory therapy care; bronchospasm requiring therapy; pleural effusion or pneumothorax (or both) necessitating drainage; segmental pulmonary collapse, as confirmed by radiography; or pneumonia necessitating antibiotic therapy. Other investigators have found that both shorter and longer periods of cessation of smoking were needed before achieving cardiovascular[220] and hematologic benefit.[221] Bluman and associates performed a retrospective chart review of 410 patients undergoing noncardiac surgery at a VA hospital.[222] Current smoking was associated with a nearly 6-fold increase in the risk of a postoperative pulmonary complication. Reduction in smoking within 1 month of surgery was not associated with a decreased risk for postoperative pulmonary complications. Nakagawa and coauthors also reported higher pulmonary complication rates in patients undergoing pulmonary surgery who quit within 4 weeks of surgery than in current smokers or those who had stopped smoking for more than 4 weeks.[223] Wong and colleagues performed a systematic review of 25 studies of smoking cessation.[224] At least 4 weeks of abstinence from smoking reduced respiratory complications, and abstinence of at least 3 to 4 weeks reduced wound healing complications. Short-term (<4 weeks) smoking cessation did not appear to affect the risk of postoperative respiratory complications.

Two randomized trials focused on smoking cessation. Wong and colleagues performed a prospective, multicenter, double-blind, placebo-controlled trial, in which 286 patients were randomized to receive varenicline or placebo.[225] A perioperative smoking cessation intervention with varenicline increased abstinence from smoking 3, 6, and 12 months after elective noncardiac surgery with no increase in serious adverse events. Lee and colleagues randomized patients to a group receiving no specific smoking cessation intervention or to an intervention group that received (1) brief counseling by the preadmission nurse, (2) brochures on smoking cessation, (3) referral to the Canadian Cancer Society's Smokers' Helpline, and (4) a free 6-week supply of transdermal nicotine replacement therapy.[226] All outcome assessors and caregivers on the operative day were blinded to group assignment. Smoking cessation occurred in 12 patients (14.3%) in the intervention group as compared with 3 patients (3.6%) in the control group (relative risk, 4.0; 95% CI, 1.2-13.7; $P = .03$). The overall rate of combined intraoperative and immediate postoperative complications was not significantly different between intervention and control groups. At follow-up 30 days postoperatively, smoking cessation was reported in 22 patients (28.6%) in the intervention group compared with 8 patients (11%) in controls (relative risk, 2.6; 95% CI, 1.2-5.5; $P = .008$).

When Skolnick and coworkers studied 602 children prospectively, exposure to passive smoking (as measured by urinary cotinine, the major metabolite of nicotine) correlated directly with airway complications. Children with the least exposure to passive smoke had the fewest complications.[210] Secondhand smoke may be a model for particulate air pollution, which can have immediate and long-term effects in increasing lung dysfunction and inflammatory stimuli throughout the body.[227,228]

Celli and associates performed a randomized prospective controlled trial of intermittent positive-pressure breathing (IPPB) versus incentive spirometry and deep-breathing exercises in 81 patients undergoing abdominal surgery.[229] The groups exposed to a respiratory therapist (regardless of the treatment given) had more than a 50% lower incidence of clinical complications (30%-33% vs. 88%) and shorter hospital stays than did the control group. Thus this demonstrates that the outcome improves when any concern about lung function is shown by someone knowledgeable in maneuvers designed to clear lung secretions.

Bartlett and coworkers randomly assigned 150 patients undergoing extensive laparotomy to 1 of 2 groups.[230] One group received preoperative instruction in and postoperative use of incentive spirometry (10 times/h). The other group received similar medical care but no incentive spirometry. Only 7 of 75 patients using incentive spirometry had postoperative pulmonary complications, as opposed to 19 of 75 in the control group. However, Lyager and colleagues randomly assigned 103 patients undergoing biliary or gastric surgery to receive either incentive spirometry with preoperative and postoperative chest physiotherapy or only preoperative and postoperative chest physiotherapy.[231] No difference in the postoperative course or pulmonary complications was found between the groups. Other studies have shown a specific benefit (i.e., greater than that provided by routine care) for chest physiotherapy and IPPB. These studies are usually poorly controlled, not randomized, or retrospective in design (or any combination); these deficiencies probably substantially bias the results toward finding a benefit in reducing postoperative pulmonary complications. Although randomized prospective studies showed no benefit or actual harm from chest physiotherapy and IPPB on the resolution of pneumonia or postoperative pulmonary complications, the studies cited earlier[212,217,229,230] and numerous retrospective studies strongly suggest that preoperative evaluation and treatment of patients with pulmonary disease actually decrease perioperative respiratory complications.

Meta-analyses have suggested a benefit of anesthetic and pain management with respect to respiratory outcomes. Rodgers and associates reviewed 141 trials involving 9559 patients who had been randomized to receive neuraxial blockade or general anesthesia. Overall mortality was significantly less frequent in the neuraxial blockade group (2.1% vs. 3.1%). The relative risk of pneumonia in the neuraxial blockade group was 0.61 (CI, 0.48-0.81), and the relative risk of respiratory depression was 0.41 (CI, 0.23-0.73).[211] Further, Neuman and colleagues examined a retrospective cohort of 18,158 patients undergoing surgery for hip fracture in 126 hospitals in New York in 2007 and 2008.[232] Patients receiving regional anesthesia experienced fewer pulmonary complications (359 [6.8%] vs. 1040 [8.1%]; $P < .005$). Regional anesthesia was associated with a lower adjusted odds of mortality (OR, 0.710; 95% CI, 0.541, 0.932; $P = .014$) and pulmonary complications (OR, 0.752; 95% CI, 0.637, 0.887; $P < .0001$) relative to general anesthesia. In subgroup analyses, regional anesthesia was associated with improved survival and fewer pulmonary complications among patients with intertrochanteric fractures but not among patients with femoral neck fractures.

Not all studies demonstrate beneficial effects of pharmacologic pretreatment. In afebrile outpatient American Society of Anesthesiologists (ASA) class I and II children with no lung disease or findings who underwent noncavitary, nonairway surgery lasting less than 3 hours, neither albuterol nor ipratropium premedication decreased adverse events.[233]

Evaluation of dyspnea is especially useful. Boushy and coworkers found that grades of preoperative dyspnea correlated with postoperative survival. (Grades of respiratory

TABLE 32.8 Grade of Dyspnea Caused by Respiratory Problems (Assessed in Terms of Walking on a Level Surface at a Normal Pace)

Category	Description
0	No dyspnea while walking on a level surface at a normal pace
I	"I am able to walk as far as I like, provided I take my time"
II	Specific (street) block limitation ("I have to stop for a while after one or two blocks")
III	Dyspnea on mild exertion ("I have to stop and rest while going from the kitchen to the bathroom")
IV	Dyspnea at rest

Modified from Boushy SF, Billing DM, North LB, et al. Clinical course related to preoperative pulmonary function in patients with bronchogenic carcinoma. *Chest.* 1971;59:383–391.

dyspnea are provided in Table 32.8.)[234] Mittman demonstrated an increased risk of death after thoracic surgery, from 8% in patients without dyspnea to 56% in patients with dyspnea.[235] Similarly, Reichel found that no patients died after pneumonectomy if they were able to complete a preoperative treadmill test for 4 minutes at the rate of 2 mph on level ground.[236] Other studies have found that the history and physical examination of an asthmatic subject can also predict the need for hospitalization.[201] Wong and colleagues found that the risk index correlated with postoperative pulmonary complications (Table 32.9).[237]

Arozullah and associates developed the first validated multifactorial risk index for postoperative respiratory failure, defined as mechanical ventilation for more than 48 hours after surgical procedures, or reintubation and mechanical ventilation after postoperative extubation.[238] In a prospective cohort study of 181,000 male veterans as part of the National Veterans Administration Surgical Quality Improvement Program, seven factors independently predicted risk (Table 32.10). With increasing numbers of risk factors present, the rate of complications increased from 0.5% (class 1) to 26.6% (class 4). Arozullah and colleagues subsequently developed a risk index for postoperative pneumonia by using data on 160,805 patients undergoing major noncardiac surgery and validated the index by using data on an additional 155,266 patients.[239] Patients were divided into five risk classes by using risk index scores (Table 32.11). Pneumonia rates were 0.2% in patients with 0 to 15 risk points, 1.2% in those with 16 to 25 risk points, 4.0% in those with 26 to 40 risk points, 9.4% in those with 41 to 55 risk points, and 15.3% in those with more than 55 risk points.

Gupta and colleagues used the American College of Surgeons NSQIP to develop a risk model for postoperative respiratory failure.[167] On multivariate logistic regression analysis, five preoperative predictors of postoperative respiratory failure were identified: type of surgery, emergency case, dependent functional status, preoperative sepsis, and higher ASA class (Table 32.12).

SPECIFIC DISEASES

Pulmonary Vascular Diseases

Pulmonary vascular diseases include pulmonary hypertension secondary to heart disease (postcapillary disorders), parenchymal lung disease (pulmonary precapillary disorders), pulmonary embolism, and cor pulmonale from COPD.[240] Optimal preoperative management of these conditions requires treatment of the underlying disease and avoidance of worsening the process.[240-242] Because pulmonary embolism can be particularly difficult to diagnose as clinical findings of pulmonary emboli are not always present or specific for the diagnosis and include a history of tachypnea, dyspnea, palpitations, syncope, chest pain, or hemoptysis. Physical examination can reveal a pleural rub, wheezing, rales, a fixed and split second heart sound, right ventricular lift, or evidence of venous thrombosis. If the ECG shows an S_1Q_3 pattern, spiral CT or lung perfusion scans can be obtained to rule out the diagnosis of pulmonary emboli. A high degree of suspicion is necessary to warrant angiography and anticoagulation or fibrinolytic therapy. If possible, the reactivity of the pulmonary vasculature should be determined because it may be enhanced or decreased by such drugs as nifedipine, hydralazine, nitroglycerin, prazosin, tolazoline, phentolamine, sildenafil citrate, and nitric oxide.

TABLE 32.9 Classification of Risk of Pulmonary Complications for Thoracic and Abdominal Procedures

Category	Points
I. EXPIRATORY SPIROGRAM

Monitoring of pulmonary artery pressure is often required. Preoperative measures should be undertaken to ensure that the patient is not exposed to conditions that elevate pulmonary vascular resistance (e.g., hypoxia, hypercapnia, acidosis, lung hyperinflation, hypothermia)[243] or increased systemic vascular resistance, as this can precipitate acute or worsened right heart failure.

Infectious Diseases of the Lung

Preoperative evaluation and treatment should follow the basic guidelines outlined in the introduction to this section and in Chapter 31. Treatment of the underlying disease should be completed before all but emergency surgery is performed.

Even though elective surgery should be postponed whenever infectious diseases of the lung are present, patients undergoing emergency surgery can have nosocomial infections and immunocompromised systems. The predominant pathogens for nosocomial pneumonia are gram-negative bacilli, *Staphylococcus aureus*, *Haemophilus influenzae*, anaerobes, and pneumococci. Previously, the incidence of tuberculosis increased in the late 1980s and in the 1990s, probably because of reactivation in patients infected with HIV, through increased funding and directly observed antituberculosis treatment the incidence has steadily declined. Tuberculosis can lead to chronic pulmonary and systemic symptoms. Affected patients may have malaise, headache, fever, hemoptysis, and extrapulmonary diseases affecting the skin, cervical lymph nodes, kidneys, pericardium, and meninges. Active disease is treated with four-drug therapy: isoniazid, pyrazinamide, ethambutol or streptomycin, and rifampin for 9 months. Therapy should probably be started preoperatively.

Management of these emergency patients (many of whom have adult respiratory distress syndrome [ARDS]) before they are brought to the operating room may include initiation of antiinfective therapy, optimization of fluid status, facilitation of gas exchange, and therapy for the underlying pathophysiologic process.

Chronic Diseases of the Lung

Treatment of COPD may include the use of short and long acting β-adrenergic drugs, parasympatholytic agents (especially for exercise-induced asthma), systemic or inhaled corticosteroids, and leukotriene antagonists. An estimated

5% of this population has bronchospasm. Some investigators recommend using inhaled bronchodilators as first-line drugs and reducing the dose of inhaled steroids, such as beclomethasone dipropionate, budesonide, mometasone, and fluticasone, which are inactivated after absorption. However, in large doses, these "inhaled" steroids can suppress adrenal function, and supplemental systemic corticosteroids may be needed at times of stress (see the earlier discussion in the section on adrenocortical malfunction). Preoperative assessment must include gaining knowledge of drug regimens and their effects and education of the patient regarding proper use of an inhaler (Box 32.4), given that these drugs can interact dangerously with anesthetics (see the last section of this chapter) or can be used inappropriately and therefore produce side effects without maximum benefit.[199-209] No known interaction between the inhaled anticholinergic ipratropium bromide and muscle relaxants has been reported. An estimated 10% of asthmatic patients exhibit sensitivity to aspirin and may react not only to compounds containing aspirin but also to tartrazine, yellow dye

BOX 32.4 Procedures for Correct Use of a Metered-Dose Inhaler

Remove the cap and hold the inhaler upright.
Shake the inhaler.
Tilt the head back slightly and exhale steadily to functional residual capacity.
Position the inhaler by using a spacer between the actuator and the mouth.
Press down on the inhaler while taking a slow, deep breath (3-5 s).
Hold the full inspiration for at least 5 and up to 10 s, if possible, to allow the medication to reach deeply into the lungs.
Repeat inhalations as directed. Waiting 1 min after inhalation of the bronchodilator may permit subsequent inhalations to penetrate more deeply into the lungs and is necessary to ensure proper delivery of the dose. Rinse your mouth and expectorate after using the inhaler.

number five, indomethacin, other nonsteroidal antiinflammatory drugs, and aminopyrine.[244]

Cystic fibrosis is characterized by dilatation and hypertrophy of the bronchial glands, mucous plugging of the peripheral airways, and frequently, bronchitis, bronchiectasis, and bronchiolectasis. For all these conditions, the measures recommended earlier in this section, as well as appropriate hydration to allow mobilization of secretions, constitute optimal preprocedure therapy.

Surgical resection is the primary therapy for non–small cell carcinomas (e.g., adenocarcinoma, squamous cell carcinoma, and large cell carcinoma). These carcinomas account for 75% of all lung carcinomas, 12% of all malignant tumors, and 20% of all cancer deaths in the United States.[245] Success of surgery can be predicted by the stage of the tumor.

The combination of chemotherapy and radiation therapy is the current treatment of choice for small cell carcinomas of the lung.[246] Oat cell (small cell) carcinoma of the lung and bronchial adenomas are known for their secretion of endocrinologically active substances, such as ACTH-like hormones. Squamous cell cancers in the superior pulmonary sulcus produce Horner syndrome, as well as characteristic pain in areas served by the eighth cervical nerves and first and second thoracic nerves. These tumors are now treated with preoperative radiation; surgical resection leads to an almost 30% "cure" rate. For all these patients, their preoperative assessment should be viewed as a "three-legged stool," including lung mechanics, parenchymal function, and cardiopulmonary reserve.

Anaphylaxis, Anaphylactoid Responses, and Allergic Disorders Other than Those Related to Lung Diseases and Asthma

Anaphylactic and Anaphylactoid Reactions. Anaphylaxis is a severe life-threatening allergic reaction. Allergic applies to immunologically mediated reactions, as opposed to those caused by pharmacologic idiosyncrasy, direct toxicity or drug overdosage, or drug-drug interaction.[247-249] Anaphylaxis is the typical immediate hypersensitivity reaction (type I) produced by immunoglobulin E (IgE) mediated release of pharmacologically active substances. These mediators in turn produce specific end-organ responses in the skin (urticaria), the respiratory system (bronchospasm and upper airway edema), and the cardiovascular system (vasodilation, changes in inotropy, and increased capillary permeability). Vasodilation occurs at the level of the capillary and postcapillary venule and leads to erythema, edema, and smooth muscle contraction. This clinical syndrome is called *anaphylaxis*. By contrast, an *anaphylactoid reaction* denotes an identical or very similar clinical response that is not mediated by IgE or (usually) an antigen-antibody process.[248,249] A large perioperative database review found that hemodynamically significant anaphylaxis occurred in 1 of every 8400 cases.[249a] Further, a personal history of anaphylaxis was the best predictor of occurrence.

In anaphylactic reactions, an injected or inhaled (or ingested) substance—usually drugs, food, or insect venom—can serve as the allergen itself. Low-molecular-weight agents are believed to act as haptens that form immunologic conjugates with host proteins. The offending substance, regardless of whether it is a hapten, may be the parent compound, a nonenzymatically generated product, or a metabolic product formed in the patient's body. When an allergen binds immunospecific IgE antibodies on the surface of mast cells and basophils, histamine and eosinophilic chemotactic factors of anaphylaxis are released from storage granules in a calcium- and energy-dependent process.[248,249] Other chemical mediators are rapidly synthesized and are subsequently released in response to cellular activation. These mediators include the following: slow-reacting substance of anaphylaxis, which is a combination of three leukotrienes; other leukotrienes;[248,249] kinins; platelet-activating factors; adenosine; chemotactic factors; heparin; tryptase; chymase; and prostaglandins, including the potent bronchoconstrictor prostaglandin D_2; eosinophil growth and activating factors; mast cell growth factors; and proinflammatory and other factors that contribute to the IgE isotype switch.

The end-organ effects of the mediators produce the clinical syndrome of anaphylaxis. Usually, a first wave of symptoms, including those caused by vasodilation and a feeling of impending doom, is quickly followed by a second wave as the cascade of mediators amplifies the reactions. In a sensitized patient, onset of the signs and symptoms caused by these mediators is usually immediate but may be delayed 2 to 15 minutes or, in rare instances, as long as 2.5 hours after the parenteral injection of antigen.[250,251] After oral administration, manifestations may occur at unpredictable times.

Mast cell proliferation, together with severe progressive inflammation, contributes to the worsening of symptoms that occurs even after an allergen load is no longer present. The antigen present in cells and lymphocytes, as well as activated mast cells, starts to induce the production of cytokines. These proinflammatory cytokines recruit more inflammatory cells, a process that leads to tissue edema and mediates a second wave of mast cell degranulation. This second wave can promote the recurrence of severe symptoms 6 to 8 hours later and necessitates, some believe, at least 8 hours of continued ICU-like observation.

In addition, biologically active mediators can be generated by multiple effector processes to produce an anaphylactoid reaction. Activation of the blood coagulation and fibrinolytic systems, the kinin-generating sequence, or the complement cascade can produce the same inflammatory substances that result in an anaphylactic reaction. The two mechanisms known to activate the complement system are called classical and alternative. The classical pathway can be initiated through IgG or IgM (transfusion reactions) or plasmin. The alternative pathway can be activated by lipopolysaccharides (endotoxin), drugs (Althesin), radiographic contrast media,[252] membranes (nylon tricot membranes for bubble oxygenators), cellophane membranes of dialyzers, vascular graft material,[253] latex or latex-containing products,[254,255] and perfluorocarbon artificial blood.

Muscle relaxants were previously believed to be the most common drug associated with anaphylaxis, though recent evidence supports protamine and antibiotics with increased risk.[249a] However, this may change with the recent approval of sugammadex as one of the primary concerns regarding the delaying its approval in the United States was "hypersensitivity reactions," which includes anaphylaxis. Latex continues to account for a significant number of these reactions, and the incidence of intraoperative anaphylaxis caused by latex is increasing. In addition, histamine can be liberated independent of immunologic reactions.[256] Mast cells and basophils release histamine in response to chemicals or drugs. Most narcotics can release histamine,[256] and they can produce an anaphylactoid reaction, as can radiographic contrast media.[252] What makes some patients more susceptible to the release of histamine in response to drugs is unknown, but hereditary and environmental factors may play a role.

Intravenous contrast material is probably the most frequently used agent that causes anaphylactoid reactions. Because diagnostic (skin and other) tests are helpful only in IgE-mediated reactions, pretesting is not useful for contrast reactions. Pretreatment with diphenhydramine, cimetidine (or ranitidine), and corticosteroids has been reported to be useful in preventing or ameliorating anaphylactoid reactions to intravenous contrast material.[252,257] Unfortunately, very large doses of steroids (1 g of methylprednisolone intravenously) may be necessary to obtain a beneficial effect, though the efficacy of large-dose steroid therapy has not been confirmed.[258] Other common substances associated with anaphylactic or anaphylactoid reactions that may merit preoperative therapy include antibiotics, intravascular volume expanders, and blood products.[258] The anesthesiologist should always be prepared perioperatively to treat an anaphylactic or anaphylactoid response.

Minimizing Risks Preoperatively. Although virtually all evidence on this subject is merely anecdotal, enough consistent thought recurs through the literature to justify proposing an optimal approach to these problems. First, predisposing factors should be sought; patients with a history of atopy or allergic rhinitis should be suspected of being at risk. Other risk factors of note include multiple previous procedures, history of spina bifida, history of asthma, food allergies associated with latex allergy (including avocado, kiwi, banana, pineapple, papaya, chestnut, and buckwheat), systemic mastocytosis, and hereditary angioedema.[258a] Because anaphylactic and anaphylactoid reactions to contrast media occur 5 to 10 times more frequently in patients with a previously suspected reaction, consideration should be given to the administration of low-osmotic agents and both H_1- and H_2-receptor antagonists for 16 to 24 hours before exposing these patients to a suspected allergen. H_1-receptor antagonists appear to require this much time to act on the receptor. Volume status can be optimized,[248] and perhaps large doses of steroids (1 g of hydrocortisone) should also be administered before exposing patients to agents associated with a high incidence of anaphylactic or anaphylactoid reactions.[258] Older patients and patients taking β-adrenergic blocking drugs present special problems; they are at higher risk of having complications from both pretreatment (especially vigorous hydration) and therapy for anaphylactic reactions (glucagon is useful here to overcome epinephrine resistance) and are less responsive to treatment regimens.[259] One approach is to avoid drugs likely to trigger anaphylactic or anaphylactoid reactions or alter the treatment protocol for this group. Drawing blood for later analysis, especially of tryptase, can be useful in clarifying the diagnosis.[260]

With the increasing incidence of latex hypersensitivity, attempts have been made to make much of the operating room environment latex free; however, costs and preferences have resulted in the continued use of latex-containing gloves in many hospitals. Nonetheless, more hospitals are totally latex free. In allergic patients, care should be taken to ensure that no latex-containing products are present in the operating room.

Primary Immunodeficiency Diseases

Primary immunodeficiency diseases usually manifest early in life as recurrent infections. Along with survival achieved with antibiotic and antibody treatment have come new prominent features: cancer and allergic and autoimmune disorders.

Hereditary angioedema is an autosomal dominant genetic disease characterized by episodes of angioedema involving the subcutaneous tissues and submucosa of the GI tract and airway and often manifested as abdominal pain. These patients have a functionally impotent inhibitor or deficiency of an inhibitor to complement component C1 leading to an overproduction of bradykinin resulting in vascular permeability. The most feared complication for the anesthesiologist is airway edema resulting in an unexpected difficult airway.[260a] The mainstay of treatment of an acute attack is supportive because epinephrine, antihistamines, and corticosteroids often fail to work. The severity of attacks can be prevented or decreased by drugs that are either antifibrinolytics (e.g., ε-aminocaproic acid [EACA] and tranexamic acid) or attenuated androgens (e.g., danazol and stanozolol). Because trauma can precipitate acute attacks, prophylactic therapy with plasma derived C1-INH, attenuated androgens, antifibrinolytics, or all three is recommended before elective surgery; a repeat dose of C1-INH can be given if edema develops.[260a] Fresh frozen plasma has been used during acute attacks with success because it contains C1-INH, though FFP could theoretically worsen an attack, as it contains other complement components and should only be used if no other treatment is available.[260a]

Most of the 1 in 700 persons who have selective IgA deficiency (i.e., <5 mg/dL) have repeated serious infections or connective tissue disorders. These infections commonly involve the respiratory tract (e.g., sinusitis, otitis) or GI tract (manifested as diarrhea, malabsorption, or both). If the patient has rheumatoid arthritis, Sjögren syndrome, or systemic lupus erythematosus, the anesthetist should consider the possibility of an isolated IgA deficiency;

however, patients with this disorder can be otherwise healthy. Because antibodies to IgA may develop in these patients if they were previously exposed to IgA (as could occur from a previous blood transfusion), subsequent blood transfusions can cause anaphylaxis, even when they contain washed erythrocytes. Transfusions should therefore consist of blood donated by another IgA-deficient patient.

Many immunomodulators are now being given to augment cancer treatments[261]; no interactions among these modulators, no effects on the incidence of immune reactions during anesthesia, and no interactions with anesthetic effects have been reported except those regarding immunosuppressant drugs (see the last section of this chapter).

Immunonutrition is increasingly being used preprocedurally by patients and prescribed by providers to decrease inflammatory responses.[254] Whereas excellent data on the benefits of probiotics in changing the intestinal milieu to decrease inflammation can be found, data on probiotics' role in prevention of intestinal complications, improvement in wound healing, incidence of perioperative infections is under investigation, though benefits may outweigh the risks.[261a-c]

Diseases of the Central Nervous System, Neuromuscular Diseases, and Psychiatric Disorders

Evaluation of a patient with neurologic or psychiatric disease can be found in Chapter 31. Information gathered from the history that warrants further investigation includes a previous need for postoperative ventilation in a patient without inordinate lung disease, which indicates the possibility of metabolic neurologic disorders such as porphyria, myopathies, neuropathies, and neuromuscular disorders such as myasthenia gravis. Other historical information warranting further investigation includes the use of drugs such as the following: steroids; guanidine; anticonvulsant, anticoagulant, and antiplatelet drugs; lithium; tricyclic antidepressants; phenothiazines; and butyrophenones.

Although preoperative treatment of most neurologic disorders may not lessen perioperative morbidity, knowledge of the pathophysiologic characteristics of these disorders is important in planning intraoperative and postoperative management. Thus preoperative knowledge about these disorders and their associated conditions (e.g., cardiac arrhythmias with Duchenne muscular dystrophy, or respiratory and cardiac muscle weakness with dermatomyositis) may reduce perioperative morbidity. A primary goal of neurologic evaluation is to determine the site of the lesion in the nervous system. Such localization to one of four levels (supratentorial compartment, posterior fossa, spinal cord, peripheral nervous system) is essential for accurate diagnosis and appropriate management. (Disorders accompanied by increased intracranial pressure and cerebrovascular disorders are discussed in Chapters 11 and 57.)

COMA

Little is known about specific anesthetic, perioperative, or periprocedural choices that alter outcome for a comatose patient, but as for all other conditions, the cause of the coma should be known so that drugs can be avoided that may worsen the condition or that may not be metabolized because of organ dysfunction. First, the patient should be observed. Yawning, swallowing, or licking of the lips implies a "light" coma with major brainstem function intact. If consciousness is depressed but respiration, pupillary reactivity to light, and eye movements are normal and no focal motor signs are present, metabolic depression is likely. Abnormal pupillary responses may indicate hypoxia, hypothermia, local eye disease, or drug intoxication with belladonna alkaloids, narcotics, benzodiazepines, or glutethimide; pupillary responses may also be abnormal, however, after the use of eye drops. Other metabolic causes of coma include uremia, hypoglycemia, hepatic coma, alcohol ingestion, hypophosphatemia, myxedema, and hyperosmolar nonketotic coma. Except in extreme emergencies, such as uncontrolled bleeding or a perforated viscus, care should be taken to render the patient as metabolically normal as possible before the surgical procedure. This practice and documenting the findings on the chart preoperatively lessen any confusion regarding the cause of intraoperative and postoperative problems. However, too rapid correction of uremia or hyperosmolar nonketotic coma can lead to cerebral edema, a shift of water into the brain as a result of a reverse osmotic effect caused by dysequilibrium of the urea concentration.

The physical examination is extremely helpful preoperatively in assessing the prognosis. Arms flexed at the elbow (i.e., decorticate posture) imply bilateral hemisphere dysfunction but an intact brainstem, whereas extension of the legs and arms (bilateral decerebrate posture) implies bilateral damage to structures at the upper brainstem or deep hemisphere level. Seizures are often seen in patients with uremia and other metabolic encephalopathies. Hyperreflexia and upward-pointing toes suggest a structural CNS lesion or uremia, hypoglycemia, or hepatic coma; hyporeflexia and downward-pointing toes with no hemiplegia generally indicate the absence of a structural CNS lesion. It is important to compare preoperative physical examination with previous different providers' examinations, trending Glasgow Coma Scores can provide utility and standardization.

EPILEPTIC SEIZURES

A seizure is the term for the clinical event defined as a paroxysmal alteration in neurologic function caused by a synchronous, rhythmic depolarization of brain cortical neurons. Epilepsy is the condition manifested by recurrent, unprovoked seizures. Epileptic seizures result from paroxysmal neuronal discharges of abnormally excitable neurons. Six percent to 10% of individuals younger than 70 years old will experience a seizure at some time during their lifetime. Fifty percent to 70% of patients with one seizure will never have another. However, 70% of people with two seizures will have an epileptic focus, be candidates for antiseizure medications, and be subject to withdrawal seizures after anesthesia if such medications are not continued.[262] Overall, epilepsy has a prevalence of 0.5% to 1% of the population, with the highest incidence in extremes of age and in those with anatomic neurologic abnormalities.[262a]

Sometimes syncopal episodes can be mistaken for seizures, especially when interviews are compressed in the short time frame of a preoperative visit. Twenty-five percent of patients with a seizure have a normal electroencephalogram (EEG) when they are interictal; thus a negative EEG result does not indicate that someone with a seizure will not have a withdrawal seizure when emerging from anesthesia. Seizures can be generalized (arising from deep midline structures in the brainstem or thalamus, usually without an aura or focal features during the seizure), partial focal motor, or sensory (the initial discharge comes from a focal unilateral area of the brain, often preceded by an aura). As with cerebrovascular accidents and coma, knowing the origin may be crucial to understanding the pathophysiologic processes of the disease and to managing the patient's intraoperative and postoperative course.

Epileptic seizures can arise from discontinuation of sedative-hypnotic drugs or alcohol, use of narcotics, uremia, traumatic injury, neoplasms, infection, congenital malformation, birth injury, drug use (e.g., amphetamines, cocaine), hypercalcemia or hypocalcemia, blood in the ventricle or hypoxia, and vascular disease and vascular accidents. Up to 30% of patients with severe traumatic brain injury develop early seizures (within 7 days of injury).[262b] Thirty percent of epileptic seizures have no known cause. Most partial seizures are caused by structural brain abnormalities (secondary to tumor, trauma, stroke, infection, and other causes).

Most authorities believe that anticonvulsant medications should be given in the therapeutic range,[262-264] and they should be continued through the morning of the surgical procedure, even in pregnant women. They should also be given postoperatively, even in mothers who plan to breastfeed, according to guidelines published by the American Academy of Neurology. Many of the epileptic drugs, including phenytoin, carbamazepine, and phenobarbiturate, alter the hepatic metabolism of many drugs and induce cytochrome P450 enzyme activity. Drug-drug interactions are much less problematic with the newer epileptic drugs such as gabapentin and topirimate.[262] Appropriate treatment of status epilepticus refractory to antiepileptic drugs includes general anesthesia and carries high morbidity.[264] In one controlled trial, phenobarbital was more rapidly effective in controlling status epilepticus than was diazepam followed by phenytoin.[264] The frequency of side effects and of required tracheal intubation was similar for both regimens. Thus other than the use of current drug therapy and heeding precautions taken for the underlying disease, no known changes in perioperative management seem to be indicated, though many agents may possess both proconvulsant and anticonvulsant properties pending dose utilized; therefore knowledge of anesthetics agents is crucial.

INFECTIOUS DISEASES OF THE CENTRAL NERVOUS SYSTEM, DEGENERATIVE DISORDERS OF THE CENTRAL NERVOUS SYSTEM, AND HEADACHE

Many degenerative CNS disorders have been traced to slowly developing viral diseases or even the presence of certain proteins or viral particles ("prions"). No special perioperative anesthetic considerations appear to apply for infectious disorders of the CNS other than those for increased intracranial pressure and avoidance of occupational exposure and transmission of disease to healthcare workers. The appropriate prophylactic measures to take if one comes in contact with meningococcal disease or other infectious CNS diseases are still not well established. The use of *H. influenzae* type B vaccine has made meningitis an adult disease.[265]

Parkinson disease is a degenerative disorder of the CNS that may or may not be caused by a virus. Clinically, Parkinson disease, chronic manganese intoxication, phenothiazine or butyrophenone toxicity, Wilson disease, Huntington chorea, the effects of street drug toxins such as methylphenyltetrahydropyridine, and carbon monoxide encephalopathy all have similar initial features: bradykinesia, muscular rigidity, and tremor.

In Parkinson disease, therapy is directed at (1) increasing presence of dopamine, (2) increasing the neuronal release of dopamine or the receptor's response to dopamine, (3) stimulating the receptor directly with dopamine agonists (i.e., bromocriptine), (4) direct stimulation of dopaminergic tissue (i.e., deep brain stimulator), or (5) decreasing cholinergic activity. Anticholinergic agents have been the initial drugs of choice because they decrease tremor more than muscle rigidity. Dopamine does not pass the blood-brain barrier, so its precursor L-dopa (levodopa) is used. Unfortunately, L-dopa is decarboxylated to dopamine in the periphery and can cause nausea, vomiting, and arrhythmia. These side effects are diminished by the administration of α-methylhydrazine (carbidopa), a decarboxylase inhibitor that does not pass the blood-brain barrier. Refractoriness to L-dopa develops, and it is now debated whether the drug should be used only when symptoms cannot be controlled with other anticholinergic medications. "Drug holidays" have been suggested as one means of restoring the effectiveness of these compounds, but cessation of such therapy may result in marked deterioration of function and need for hospitalization. Therapy for Parkinson disease should be initiated preoperatively and be continued through the morning of the surgical procedure; such treatment seems to decrease drooling, the potential for aspiration, and ventilatory weakness.[266,267] Reinstituting therapy promptly after surgery is crucial,[263,266-270] as is avoiding drugs such as the phenothiazines and butyrophenones, which inhibit the release of dopamine or compete with dopamine at the receptor.[266] Carbidopa or levodopa in low doses (20-200 mg nightly vs. the usual 60-600 mg/day for Parkinson disease) is commonly used in the nonparkinsonian restless leg syndrome of older adults (present in 2%-5% of individuals >60 years old). This drug also should be given the night before and the night immediately after the surgical procedure. Clozapine does not appear to worsen the movement disorders of Parkinson disease and has been used postoperatively to stop levodopa-induced hallucinations. Patients with Parkinson disease may also undergo deep brain stimulation under monitored anesthesia care. Postoperatively patients with Parkinson disease benefit from early physical therapy, appropriate analgesia, pulmonary hygiene, and autonomic assessment with necessary intervention.[270a]

Dementia, a progressive decline in intellectual function, can be caused by treatable infections (e.g., syphilis, cryptococcosis, coccidioidomycosis, Lyme disease, tuberculosis), depression (a trial of antidepressants is indicated in most patients), side effects of medications (digitalis has slowed brain function more than the heart rate), myxedema, vitamin B_{12} deficiency, chronic drug or alcohol intoxication, metabolic causes (liver and renal failure), neoplasms, partially treatable infections (HIV), untreatable infections (Creutzfeldt-Jakob syndrome), or decreased acetylcholine in the cerebral cortex (Alzheimer disease). This last condition occurs in more than 0.5% of Americans.[271-274] As of 2013, some degree of Alzheimer disease affects approximately 11% of Americans aged 65 and older, and affects approximately 32% of Americans aged 85 and older.[274a] Although these patients are often given cholinergic agonists, controlled trials of these drugs have not as yet shown major significant benefit.[272,273,275] Gingko has improved subjective symptoms in 37% of patients versus 23% of those given placebo. Although further controlled trials failed to confirm its benefit in early Alzheimer disease or in healthy older individuals, gingko is still popular. Cholinergic medications improve functioning in patients with Alzheimer disease.[276] These families often desire surgery, but the interactions of these drugs and therapies with perioperative analgesic and anesthetic drug therapies are not well established. One case report noted intraoperative bradycardia in such patients with two cholinergic drugs.[277] A link may exist among Alzheimer disease, postoperative cognitive dysfunction, and inhaled anesthetics.[278,278a] Deposition of β-amyloid can occur in animals exposed to inhaled anesthetics.[279-281] Whether this link is clinically relevant in humans remains to be determined. Most reversible dementias represent either delirium (commonly infection, metabolic, or drug induced) or depression.[272,273,282] Creutzfeldt-Jakob disease (prion driven) has been transmitted inadvertently by surgical instruments and corneal transplants; the causative virus or protein particle is not inactivated by heat, disinfectants, or formaldehyde.

More than 90% of patients with chronic recurring headaches are categorized as having migraine, tension, or cluster headaches. The mechanism of tension or cluster headaches may not differ qualitatively from that of migraine headaches; all may be manifestations of labile vasomotor regulation.[283] A headache is said to be migraine if it is characterized by four of the following five "POUNDing" conditions: if it is Pulsating, if it lasts One day or more, if it is Unilateral, if Nausea occurs, and if it Disturbs daily activities.[284]

Treatment of cluster and migraine headaches centers on the use of serotonin drugs such as sumatriptan or ergotamine and its derivatives.[283-285] Other drugs that may be effective are propranolol, calcium channel inhibitors, cyproheptadine, prednisone, antihistamines, tricyclic antidepressants, phenytoin, and diuretic drugs, as well as biofeedback techniques. Giant cell arteritis, glaucoma, and all the meningitides, including Lyme disease, are other causes of headache that may benefit from preoperative treatment.[286] No other special treatment is indicated preoperatively for a patient who has a well-delineated cause for the headaches. Acute migraine attacks can sometimes be terminated by ergotamine tartrate aerosol or by injection of sumatriptan or dihydroergotamine mesylate intravenously; general anesthesia has also been used. We normally continue all prophylactic headache medicine, although the decision to continue aspirin through the morning of the surgical procedure is usually left to the surgeon.

BACK PAIN, NECK PAIN, AND SPINAL CANAL SYNDROMES

Acute spinal cord injury is discussed earlier in the section on autonomic dysfunction. Although it is a common problem, little is written about the anesthetic management of syndromes related to herniated disks, spondylosis (usually of advancing age), and the congenital narrowing of the cervical and lumbar spinal canal that gives rise to symptoms of nerve root compression. One report stresses the importance of the vascular component in the mechanism of damage to the spinal cord and hence the theoretic desirability of slight hypertension perioperatively.[287] Another report suggests the use of awake intubation, a fiberoptic bronchoscope, and monitoring of evoked potentials.[288] Patients with back pain may be receiving large doses of narcotics that may influence the anesthetic plan and necessitate the need for a perioperative multimodal analgesic approach, including the continuation of home analgesic regimens. A thoughtful preanesthetic discussion with the patient regarding analgesia following surgery is essential for a successful postsurgical regimen.

DEMYELINATING DISEASES

Demyelinating diseases constitute a diffuse group of diseases ranging from those with uncertain cause (e.g., multiple sclerosis, in which genetic, epidemiologic, and immunologic factors are probably all involved and interferon-β appears to be a promising treatment[289]) to those that follow infection, vaccination (e.g., Guillain-Barré syndrome), or antimetabolite treatment of cancer. Therefore, demyelinating diseases can have very diverse symptoms, with a risk of relapse of disease existing immediately after surgery. Because relapse may occur as a result of rapid electrolyte changes and hyperthermia in the perioperative period, such changes should be avoided and temperature tightly regulated.[289a] In addition, perioperative administration of steroids may be a protective measure.[100] Both spinal anesthesia and epidural anesthesia have been administered without problems.[290,291] Multiple sclerosis and demyelinating diseases in general are the most common causes of nontraumatic disability in young adults with a prevalence reported between 2 and 150/100,000 people.[289a] The age-adjusted survival rate is 80% of that of unaffected individuals (i.e., the average patient with multiple sclerosis ages 1.2 years for every year with the disease). No treatment alters most of these disease processes, although ACTH, steroids, interferon-β, glatiramer acetate (Copaxone), and plasmapheresis may ameliorate or abbreviate a relapse, or even alter disease progression, especially progression of multiple sclerosis and (if started within 2 weeks of onset) Guillain-Barré syndrome.[292] Such an effect is consonant with the hypothesis of an immunologic disorder as the cause of these diseases. Care should be taken to avoid succinylcholine in these patients because of the risk of hyperkalemia secondary to extrajunctional acetylcholine receptors.

METABOLIC DISEASES

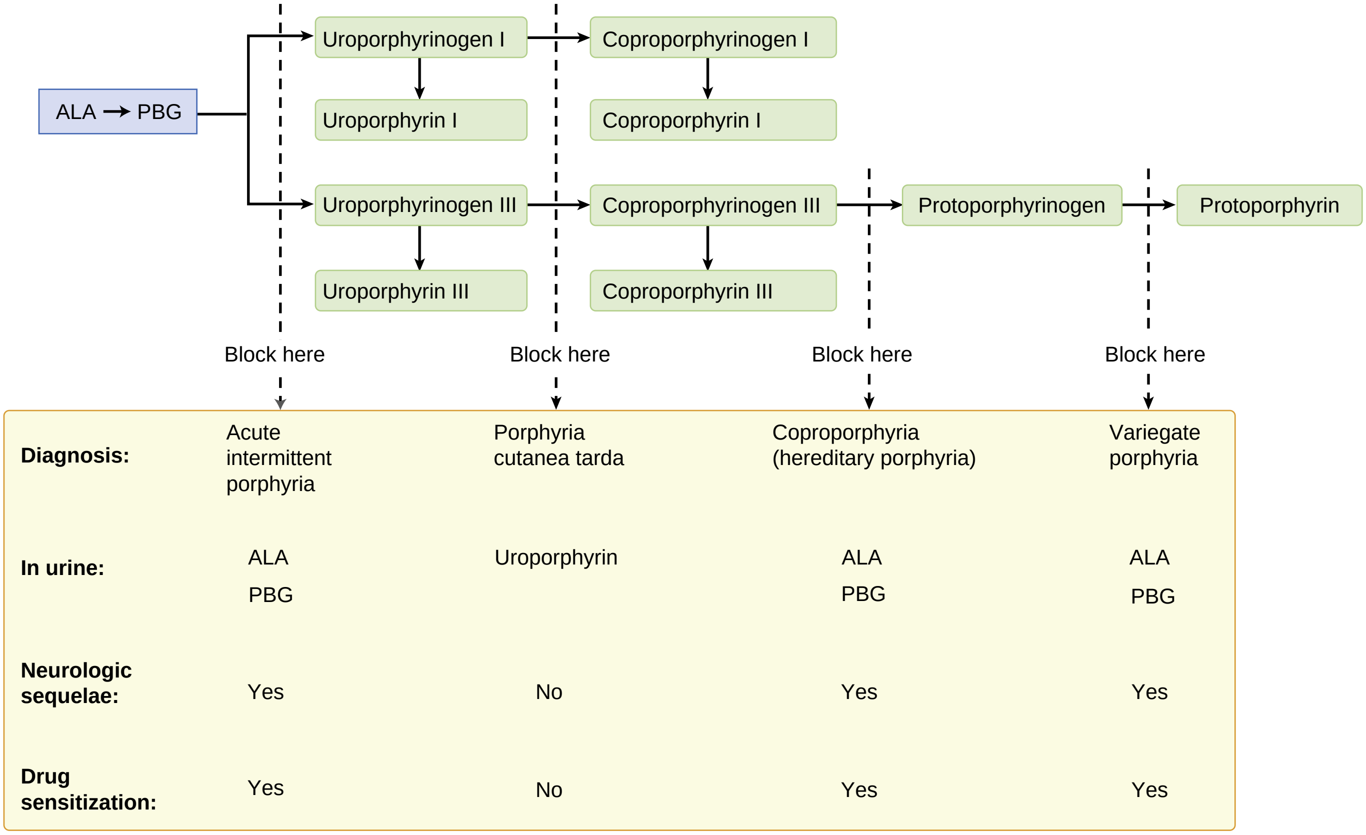
Included in the category of metabolic diseases is nervous system dysfunction secondary to porphyrias, alcoholism, uremia, hepatic failure, and vitamin B_{12} deficiency. The periodic paralysis that can accompany thyroid disease is discussed in the later section on neuromuscular disorders.

Alcoholism or heavy alcohol intake is associated with the following: acute alcoholic hepatitis, the activity of which declines as alcohol is withdrawn; myopathy and cardiomyopathy, which can be severe; and withdrawal syndromes. Within 6 to 8 hours of withdrawal, the patient may become tremulous, a state that usually subsides within days or weeks. Alcoholic hallucinosis and withdrawal seizures generally occur within 24 to 36 hours. These seizures are generalized grand mal attacks; when focal seizures occur, other causes should be sought. Delirium tremens usually appears within 72 hours of withdrawal and is often preceded by tremulousness, hallucinations, or seizures. These three symptoms, combined with perceptual distortions, insomnia, psychomotor disturbances, autonomic hyperactivity, and, in a large percentage of cases, another potentially fatal illness (e.g., bowel infarction or subdural hematoma), are components of delirium tremens. This syndrome is now treated with benzodiazepines. Nutritional disorders of alcoholism include alcoholic hypoglycemia and hypothermia, alcoholic polyneuropathy, Wernicke-Korsakoff syndrome, and cerebellar degeneration. In patients with alcoholism (i.e., those who drink at least two six packs of beer or one pint of hard alcohol/day or the equivalent), emergency surgery and anesthesia (despite alcoholic hepatitis), are not associated with worsening abnormalities in liver enzymes. In addition, approximately 20% of patients with alcoholism also have respiratory disease. Further, postoperatively these patients can have poor wound healing, altering levels of consciousness/delirium, and difficulty with analgesia.[292a] A patient who has a history of alcohol abuse therefore warrants careful examination of many systems for quantification of preoperative physical status.

Although hepatic failure can lead to coma with high-output cardiac failure, unlike uremia, it does not lead to chronic polyneuropathy. Uremic polyneuropathy is a distal symmetric sensorimotor polyneuropathy that may be improved by dialysis. The use of depolarizing muscle relaxants in patients with polyneuropathies has been questioned. We believe that patients who have neuropathy associated with uremia should not be given succinylcholine because of a possible exaggerated hyperkalemic response.

Pernicious anemia caused by vitamin B_{12} deficiency may result in subacute combined degeneration of the spinal cord; the signs are similar to those of chronic nitrous oxide toxicity. Both pernicious anemia and nitrous oxide toxicity are associated with peripheral neuropathy and disorders of the pyramidal tract and posterior column (which governs fine motor skills and the sense of body position). Combined-system disease can also occur without anemia, as can nitrous oxide toxicity in dentists and nitrous oxide abusers. Patients with vitamin B_{12} deficiency and anemia, if treated with folate, improve hematologically but progress to dementia and severe neuropathy. It may thus be prudent to give an intramuscular injection of 100 µg of vitamin B_{12} or 800 µg orally before giving folate to a patient who has signs of combined-system degeneration.[293]

The porphyrias are a constellation of metabolic diseases that result from an autosomally inherited lack of functional enzymes active in the synthesis of hemoglobin. Fig. 32.6 schematically depicts the abnormalities that result from these enzyme deficits. Type 1, 3, and 4 porphyrias can cause life-threatening neurologic abnormalities. These conditions are characterized by the presence of aminolevulinic



Diagnosis:	Acute intermittent porphyria	Porphyria cutanea tarda	Coproporphyria (hereditary porphyria)	Variegate porphyria
In urine:	ALA PBG	Uroporphyrin	ALA PBG	ALA PBG
Neurologic sequelae:	Yes	No	Yes	Yes
Drug sensitization:	Yes	No	Yes	Yes

Fig. 32.6 Schematic depiction of the functional enzyme deficits that occur in some of the porphyrias. *ALA,* Aminolevulinic acid; *PBG,* porphobilinogen.

acid (ALA) or porphobilinogen, or both, in urine; these substances do not occur in porphyria cutanea tarda, a disease that does not incur neurologic sequelae.[294] In acute intermittent porphyria, the typical pattern consists of acute attacks of colicky pain, nausea, vomiting, severe constipation, psychiatric disorders, and lesions of the lower motoneuron that can progress to bulbar paralysis. Often, these patients will have had multiple previous surgeries. Certain drugs can induce the enzyme ALA synthetase and thereby exacerbate the disease process.[295-297] Drugs considered unsafe include barbiturates (all types), phenytoin, valproic acid, carbamazepine, primidone, oral contraceptives, progestins, carisoprodol, and sprinolactone.[297a] Clonazepam, ketamine, imipramine, sulfa antibiotics, erythromycin, fluconazole, nitrofurantoin, and rifampicin are considered possibly unsafe and should be used with caution.[297a] Patients can have attacks during infection, fasting, or menstruation. Administration of glucose suppresses ALA synthetase activity and prevents or ablates acute attacks. Drugs used in anesthetic management that are reported to be safe for patients with porphyria include neostigmine, atropine, succinylcholine, nitrous oxide, procaine, propofol, etomidate, meperidine, fentanyl, morphine, droperidol, promazine, promethazine, and chlorpromazine.[295-297] Although ketamine has previously been used, postoperative psychoses attributable to the disease may be difficult to distinguish from those possibly caused by ketamine. Propofol has been used without provoking porphyria in at least two susceptible patients.[295,296]

NEUROMUSCULAR DISORDERS

Neuromuscular disorders consist of conditions affecting any major component of the motor unit: motoneuron, peripheral nerve, neuromuscular junction, and muscle. Neuropathies may involve all components of the nerve, thereby producing sensory, motor, and autonomic dysfunction, or only one component. Myopathies may involve the proximal muscles, the distal muscles, or both.

Myasthenia gravis is a disorder of the muscular system caused by partial blockade or destruction of nicotinic acetylcholine receptors by IgG antibodies. The severity of the disease correlates with the ability of antibodies to decrease the number of available acetylcholine receptors.[298] Treatment of myasthenia is usually begun with anticholinesterase drugs, but in moderate and severe disease, treatment progresses to steroids and thymectomy.[298,299] Immunosuppressive drugs and plasmapheresis are initiated if the more conservative measures fail, and intravenous immunoglobulin, a rapid-onset therapy, is reserved for acute exacerbations and myasthenic crises.[298,299]

One major problem for the anesthesiologist involves the use of muscle relaxants and their reversal.[300] Because much of the care of patients with myasthenia gravis involves tailoring the amount of anticholinesterase medication to the maximal muscle strength of the patient, derangement of the course of the patient during the surgical procedure could necessitate reassessment of the drug dosage. For that reason, all anticholinergic drugs may be withheld for 6 hours preoperatively, and medication should be reinstituted postoperatively with extreme caution because the sensitivity of these patients to such drugs may have changed. Small doses of succinylcholine can be used to facilitate endotracheal intubation; extremely small doses of nondepolarizing drugs can be used for intraoperative relaxation not achieved by regional anesthesia or volatile anesthetics. Of prime importance is monitoring neuromuscular blockade as the guide for muscle relaxant administration and their reversal. Previously, controlled mechanical ventilation was frequently required for 24 to 48 hours postoperatively; however, immediate extubation has become more common.[299-301] Postoperative ventilation is especially important in patients with myasthenia gravis of more than 6 years' duration, COPD, a daily pyridostigmine requirement of 750 mg in association with significant bulbar weakness, and vital capacity of less than 40 mL/kg (PFTs are an important part of the preoperative workup).[301] One study in myasthenic patients found rapid recovery of neuromuscular function in patients receiving rocuronium when sugammadex was used for reversal.[302] This combination could be a rational alternative for myasthenic patients for whom neuromuscular blockade is mandatory during surgical procedures. Another study found that epidural analgesia intra- and postoperatively reduced the requirement of mechanical ventilation following thymectomy, though this was retrospective in nature.[302a] This technique may provide benefit and allow for minimal use of muscle relaxation.

Lambert-Eaton syndrome (myasthenic syndrome) is characterized by proximal limb muscle weakness and is associated with antibodies directed against the voltage-gated calcium channels in presynaptic nerve terminals. Strength or reflexes typically increase with repetitive effort, as affected patients exhibit decreased release of acetylcholine at the neuromuscular junction and repetitive use increases the available junctional acetylcholine. Guanidine therapy enhances the release of acetylcholine from nerve terminals and improves strength. Men with this syndrome generally have small cell carcinoma of the lung or other malignant disease, whereas women often have malignant disease, sarcoidosis, thyroiditis, or a collagen-related vascular disease. In addition, these patients have increased sensitivity to both depolarizing and nondepolarizing muscle relaxants.[303] These patients have an increased risk of prolonged muscle weakness or postoperative respiratory failure after exposure to neuromuscular blocking drugs, particularly when untreated preoperatively.[303a] Lambert-Eaton syndrome is also associated with an autonomic nervous system defect manifested by gastroparesis, orthostatic hypotension, and urinary retention.

Dermatomyositis and polymyositis are characterized by proximal limb muscle weakness with dysphagia. These conditions are associated with malignant disease or collagen-related vascular disease and often involve respiratory and cardiac muscle.

Periodic paralysis is another disease in which sensitivity to muscle relaxants increases. Periodic weakness starts in childhood or adolescence and is precipitated by rest after exercise, sleep, cold, surgery, or pregnancy. Hypokalemic and hyperkalemic forms exist and are associated with cardiac arrhythmias. Like thyrotoxic periodic paralysis, these hypokalemic and hyperkalemic forms usually spare the respiratory muscles. Anesthetic management consists of minimizing stress, maintaining normal fluid and electrolyte status, and controlling body temperature.[303-306]

Patients with muscular dystrophy now survive into their late 20s or early 30s. Because the disease involves the muscles themselves and not their innervation, conduction anesthesia cannot produce adequate relaxation of tonic muscles. Gastric dilation is also a problem. As with the other forms of muscular dystrophy, most problems in myotonic dystrophy arise from cardiac arrhythmias and inadequacy of the respiratory muscles.[307] The preoperative workup for all muscular dystrophies should include echocardiography and PFTs.[307a] For all the forms of muscular dystrophy, problems have been related to exaggerated release of serum potassium after the administration of depolarizing muscle relaxants. Volatile anesthetics are associated with anesthesia-induced rhabdomyolysis, hyperkalemia, and cardiac arrest; therefore, total intravenous anesthesia is the preferred method of general anesthesia. Of note, sugammadex has been used with success for muscle relaxation reversal.[307a]

Malignant hyperthermia in the patient or in a relative of the patient merits careful history taking and at least consideration of performing a test for susceptibility to the condition. Prophylaxis with intravenous dantrolene sodium may also be warranted with high risk patients. Through genotyping malignant hyperthermia has been associated with central core disease, multiminicore myopathy, congenital myopathy with cores and rods, centronuclear myopathy, congenital fiber type disproportion, King-Denborough syndrome, periodic paralysis, nemaline rod myopathy, Native American myopathy, and idiopathic hyperCKemia.[307b] Further genotyping has demonstrated that Duchene muscular dystrophy and Beck muscular dystrophy are better classified as a nonmalignant hyperthermia anesthetic-induced rhabdomyolysis, despite similar clinical appearances.[307b] Appropriate preparation for a patient with previous masseter spasm, or trismus, remains a matter of considerable debate. Malignant hyperthermia occurs most frequently in children and adolescents; the incidence is 1 in 14,000 administrations of anesthesia. The incidence increases to 1 in 2500 patients requiring strabismus surgery.

DOWN SYNDROME

Down syndrome (trisomy 21) occurs once in 1000 live births. It is associated with congenital cardiac lesions such as endocardial cushion defects (40%), ventricular septal defects (27%), patent ductus arteriosus (12%), and tetralogy of Fallot (8%). Prophylactic antibiotics should be used before predictable bacteremic events. Down syndrome is also associated with upper respiratory infections, with atlantooccipital instability (in approximately 15% of patients[308-311]) and laxity of other joints, with thyroid hypofunction (50%), with an increased incidence of subglottic stenosis, and with enlargement of the tongue (or a decreased oral cavity size for a normal-sized tongue).[310,312] Often, the atlantooccipital instability is asymptomatic and undiagnosed, so all patients should be treated as though they have atlantooccipital instability. No abnormal responses to anesthetic agents or anesthetic adjuvants have been substantiated. A reported sensitivity to atropine has been disproved, although administration of atropine to any patient receiving digoxin for atrial fibrillation should be done with care.[312] Examination for the conditions associated with Down syndrome should precede surgery.

PREOPERATIVE PREDICTION OF INCREASED INTRACRANIAL PRESSURE DURING NEUROSURGERY

Symptoms and signs of increased intracranial pressure include morning headache or headache made worse by coughing, nausea, vomiting, disturbances in consciousness, history of large tumors, tumors involving the brainstem, neck rigidity, and papilledema. Patients with these signs, large ventricles (as seen on radiography or images of the brain), or edema surrounding supratentorial tumors should be considered at risk for intraoperative intracranial hypertension. These patients may benefit from preoperative treatment or anesthetic management that assumes this possibility.[313]

MENTAL DISORDERS

Perhaps the most important preoperative consideration for patients with mental disorders, in addition to developing rapport, is understanding their specific drug therapy and its effects and side effects. Lithium, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), other antidepressants that defy classification (e.g., bupropion), phenothiazines, butyrophenones, and MAOIs are used in these patients.[314] These drugs have potent effects and side effects that are discussed in the last section of this chapter, on drug therapy.

Renal Disease and Electrolyte Disorders

The anesthesiologist has an important role to play in preventing the onset and consequences of renal failure and its initiators. The linking of renal failure to electrolyte disorders is more obvious: the kidney is the primary organ for regulating body osmolality and fluid volume and has a major role in excretion of the end products of metabolism. In performing these functions, the kidney becomes intimately involved in the excretion of electrolytes.

A patient with renal insufficiency whose own kidneys are still functioning is distinct not only from a patient with end-stage renal disease whose renal functions are provided by dialysis but also from a patient who has a transplanted kidney. These three groups of patients require very different preoperative preparation. In addition, acute changes in renal function present quite a different problem than do chronic alterations in function. Certain renal diseases require different preoperative preparation than others, but generally, renal disease of any origin presents the same preoperative problems.

RENAL DISEASE

Causes and Systemic Effects of Renal Disorders

Nephrotic syndrome may develop in patients with glomerular diseases without disturbing tubular function. The soundness of tubular function is an important consideration because tubular dysfunction with attendant uremia presents problems quite different from those presented by glomerular disease with only nephrotic syndrome. This is not to minimize the adverse effects of glomerular disease; nephrotic syndrome consists of massive proteinuria and consequent hypoalbuminemia. The resulting reduction in plasma oncotic pressure diminishes plasma volume and calls forth compensatory mechanisms that result in retention of sodium and water. As a result, a common clinical finding in nephrotic syndrome is diffuse edema. Thus patients with nephrotic syndrome may have excess total-body water and decreased intravascular volume. In addition, diuretics are often given in an attempt to decrease edema. Although serum creatinine and creatinine clearance estimations have limitations as indices of the GFR (insulin clearance is the reference standard), these measurements are, for now, the most readily available to the anesthesiologist. Plasma creatinine levels reflect endogenous muscle catabolism and dietary intake, as well as urinary excretion. Urinary excretion depends on both filtration and secretion by the kidney. Drugs that are commonly used in the preoperative and perioperative periods can distort this measure of glomerular filtration. Moreover, the commonly used methods for measuring creatinine have a 95% confidence limit of greater than 20% for a GFR higher than 30 mL/min. Thus a normal creatinine level of 1.3 mg/dL may give a measured value ranging from 1.1 to 1.5 mg/dL.

Furthermore, in patients with nephrotic syndrome in whom renal tubular function has been preserved, hypovolemia appears to be a significant cause of deteriorating tubular renal function.[315-317] No randomized study has shown that close control of intravascular volume status in these groups of patients preserves renal tubular function (or any other measure of perioperative morbidity) to a greater degree than does less rigid control.

Uremia, the end result of renal tubular failure (i.e., failure of the concentrating, diluting, acidifying, and filtering functions) manifests in many ways. Changes occur in the cardiovascular, immunologic, hematologic, neuromuscular, pulmonary, and endocrine systems, as well as in bone. These alterations are ascribed either to the toxic end products of protein metabolism or to an imbalance in functioning of the kidney. As the number of functioning nephrons diminishes, the still-functioning nephrons attempt to increase some solute and body composition preservation functions at the expense of other functions, such as excretion of phosphate. The accumulation of phosphate increases PTH levels, which in turn produce osteodystrophy. Osteodystrophy can be managed by (1) restriction of dietary phosphate, (2) the use of binding agents (e.g., aluminum hydroxide or carbonate) that bind with intestinal phosphate, (3) calcium supplementation, or (4) parathyroidectomy.

Certain alterations in patients with uremia, such as neuropathy, are most logically attributed to an accumulation of toxic metabolites. Peripheral neuropathy is most often sensory and involves the lower extremities, but it may also be motor; peripheral neuropathies are frequently improved with hemodialysis and can be dramatically reversed with renal transplantation. Tubular function is commonly assessed by acidifying and concentrating capabilities.[318] Although such tests are crude, these capabilities are usually readily evaluated by measuring urine pH and specific gravity. Along with the altered volume status and cardiac complications in uremic patients, autonomic neuropathy may contribute to hypotension during anesthesia. Atherosclerosis is often accelerated in uremic patients; hypertension, with its attendant consequences, is very common.

Cardiac failure frequently occurs in uremic patients because of the presence of many adverse conditions: anemia with increasing myocardial work, hypertension, atherosclerosis, and altered volume status. Pericarditis can manifest by pericardial rub alone or by pain (with or without hemorrhage), the ECG will show diffuse ST changes in multiple coronary distributions—when available, these should be correlated to previous coronary catherization findings. Cardiac tamponade should be ruled out on the basis of clinical features and by echocardiography if this diagnosis is seriously suspected preoperatively. In addition, cardiac tamponade should be treated or planned for preoperatively.

If anemia is present, its severity generally parallels the degree of uremia; chronically uremic patients seem to adapt well to anemia. No hard data have substantiated the need to give a preoperative blood transfusion to a chronically uremic patient, even when the preoperative hemoglobin is approaching 7 g/dL. Even in nonuremic patients in an ICU and during cardiac surgery, randomized trials were unable to demonstrate improved outcomes with a liberal transfusion strategy,[319] and transfusions increase the risk for immune system compromise.[320,321a] In uremic patients, coagulation and platelet adhesiveness may be abnormal, and factor VIII and von Willebrand factor activity may be decreased; often, these patients may require DDAVP for enhancement of coagulation intraoperatively. However, DDAVP must be used with caution as it can lead to fluid retention and hypotension with rapid infusion.[321b]

Uremic patients exhibit a wide variety of metabolic and endocrinologic disorders in addition to hyperparathyroidism, including impaired carbohydrate tolerance, insulin resistance, type IV hyperlipoproteinemia, autonomic insufficiency, hyperkalemia, and anion-gap acidosis (caused by an inability of the kidneys to reabsorb filtered bicarbonate and excrete sufficient ammonium into urine). Furthermore, the excretion and pharmacokinetics of drugs are different in uremic patients than in normal patients. In addition, complications of hemodialysis include nutritional deficiencies, electrolyte and fluid imbalances, and mental disorders. Because these conditions can lead to serious perioperative morbidity, they should be evaluated preoperatively.

As with uremic patients, preoperative optimization of volume status is paramount in patients with kidney stones, and both are affected by carbohydrate intolerance.[321,322] Seventy-five percent of all kidney stones are composed of calcium oxalate. Patients with these stones frequently take diuretic drugs, consume calcium- and citrate-rich foods, and restrict salt intake. Prevention of dehydration by institution of intravenous fluid therapy along with restricted oral intake of protein may be as important for these patients as it is for patients with struvite or uric acid stones. Struvite stones often result from urinary infection. Uric acid stones can be prevented by treatment with allopurinol, by preoperative hydration, or by alkalinization of urine. Acidosis may contribute to stone formation. Again, optimal intravascular volume status is important in preventing stones and preserving renal function. More thorough discussion of renal function and physiology is provided in Chapter 17. Chapter 59 deals with the complexities of managing patients for renal surgery and other urologic procedures.

Creatinine clearance in conjunction with free water clearance appears to be the most accurate way of quantifying, for pharmacokinetic purposes, the degree of decreased renal function.[322] For a patient with stable renal function, creatinine clearance, which is a rough estimate of GFR, can be approximated by noting the serum creatinine level: a doubling of the creatinine level represents a halving of the GFR. Thus a patient with a stable serum creatinine level of 2 mg/dL would have a GFR of approximately 60 mL/min. A stable serum creatinine level of 4 mg/dL would accompany a GFR of approximately 30 mL/min, and a stable serum creatinine level of 8 mg/dL would accompany a GFR of 15 mL/min or less.

$$\text{Creatinine clearance} = \frac{(140 - \text{Age [yr]}) \times \text{Body weight (kg)}}{72 \times \text{serum creatinine} \left(\frac{\text{mg}}{\text{dL}}\right)}$$

$$\text{Free water clearance} = \text{Urine flow (mL/hour)}$$

$$\frac{\text{Urine osmolality} \left(\frac{\text{mOsm}}{\text{L}}\right) \times \text{Urine flow} \left(\frac{\text{mL}}{\text{hour}}\right)}{\text{Plasma osmolality} \left(\frac{\text{mOsm}}{\text{L}}\right)}$$

Free water clearance is a measure of renal concentrating ability, and it is normally −25 to +100 mL/h; it becomes more positive in renal insufficiency states. It may also become more positive in patients who have a head injury or high blood alcohol levels or in those undergoing aggressive fluid infusion or administration of diuretics.[323]

Patients With Insufficient but Functioning Kidneys

One of the greatest challenges for the anesthesiologist is presented by patients with insufficient renal function whose renal function must be preserved during surgical procedures. In addition, the presence of chronic renal failure is associated with higher rates of perioperative cardiac morbidity, which may warrant further evaluation for the presence of occult CAD.[324] The many uremic symptoms and great perioperative morbidity associated with uremia can probably be avoided by attention to detail in the preoperative and perioperative management of patients with insufficient but still functioning kidneys.[315-317]

First, studies demonstrate that acute postoperative renal failure is associated with an extremely high mortality rate.[325] The development of perioperative renal dysfunction has multiple risk factors, the most important of which include preexisting renal disease, heart surgery involving cardiopulmonary bypass or aortic surgery involving cross-clamping of the thoracic or abdominal aorta, and ongoing sepsis. Perioperative renal dysfunction accounts for upward of 40% of all in-hospital cases of acute kidney injury.[325a]

Moreover, acute perioperative renal failure is most likely to occur in patients who have renal insufficiency before the surgical procedure, are older than 60 years, and have preoperative left ventricular dysfunction.[323,325] Proper preoperative hydration probably decreases mortality after acute renal failure induced by radiocontrast agents.[317] Clues to the presence of hypovolemia or hypervolemia should be sought from the history and physical examination (e.g., weight loss or gain, thirst, edema, orthostatic hypotension and tachycardia, flat neck veins, dry mucous membranes, decreased skin turgor). Other causes of deterioration in function in chronic renal insufficiency are low cardiac output or low renal blood flow (in prerenal azotemia, whether because of cardiac failure or fluid depletion from diuretic drugs, BUN often increases disproportionately to increases in creatinine), urinary tract infection, use of nephrotoxic drugs, hypercalcemia, and hyperuricemia. These conditions and drugs should be avoided; if any of these conditions exist, they should be treated preoperatively.

Management of patients with renal disease is discussed in Chapter 59.

Patients Undergoing Dialysis

Patients with chronic (and at times acute) renal failure require renal replacement therapy, including conventional intermittent hemodialysis, peritoneal dialysis, and continuous renal replacement therapy (CRRT). CRRT includes a wide variety of techniques whose perioperative management has been reviewed (Table 32.13).[326] Although the primary indication for CRRT is acute renal failure, it can also be used for fluid clearance, correction of electrolyte abnormalities, management of metabolic acidosis, and removal of some toxins. It can be used in surgical patients without significant hemodynamic abnormalities. These patients may return to the operating room, and their assessment and management may be complicated by the underlying disease and the use of systemic anticoagulation to prevent filter and circuit clotting. In patients undergoing intermittent treatment with hemodialysis or peritoneal dialysis, the procedure is discontinued before entering the operating room. For patients on CRRT, the anesthesiologist must determine the appropriateness of discontinuing the therapy. With short procedures,

TABLE 32.13 Characteristics of Renal Replacement Therapy

Renal Replacement Therapy	Blood Pump	Replacement Fluid (RF)/Dialysate (D)	Intraoperative Use
Conventional intermittent hemodialysis	Yes	D	No
Peritoneal dialysis	No	D	No
Slow continuous ultrafiltration	Yes/no	None	Yes
Continuous arteriovenous hemodialysis	No	D	No
Continuous arteriovenous hemodiafiltration	No	RF/D	No
Continuous venovenous hemofiltration	Yes	RF	Yes
Continuous venovenous hemodialysis	Yes	D	Yes
Continuous venovenous hemodiafiltration	Yes	RF/D	Yes

From Petroni KC, Cohen NH. Continuous renal replacement therapy: anesthetic implications. *Anesth Analg.* 2002;94:1288–1297.

the therapy can usually be stopped safely provided the initial indication for therapy has improved (i.e., resolution of acidosis or hyperkalemia). If continued, CRRT can also be used to manage fluids during the surgical procedure by changing the dialysate, but the effect on drug dosing must be recognized. In addition to effects on renal elimination of drugs, CRRT has effects resulting from changes in protein binding and volume of distribution, as well as drug removal effects from membrane permeability, membrane surface area, the ultrafiltration rate, and the dialysate flow rate.

Because a patient undergoing conventional dialysis has already lost natural renal functioning, the emphasis in preoperative assessment shifts toward protecting other organ systems and optimally maintaining vascular access sites for cannulation. Usually, this does not require invasive monitoring. Emphasis is placed on intravascular fluid volume and electrolyte status, which can be ascertained by knowing when the patient last underwent dialysis, how much weight was normally gained or lost with dialysis, whether the fluid loss was peritoneal or intravascular, and what electrolyte composition the blood was dialyzed against. Although preoperative dialysis may benefit patients who have hyperkalemia, hypercalcemia, acidosis, neuropathy, and fluid overload, the resulting dysequilibrium between fluid and electrolytes can cause problems. Because hypovolemia induced by dialysis can lead to intraoperative hypotension, we try to avoid weight and fluid reduction in patients undergoing preoperative dialysis focusing on clearance of solutes and management of acid-base balance.

When renal transplant recipients have subsequent surgical procedures, the status of their renal function must be determined (i.e., whether they have normal renal function, insufficient but still functioning kidneys, or end-stage renal disease requiring hemodialysis). Descriptions of side effects of immunosuppressive drugs should also be sought. The drugs used preoperatively and intraoperatively to prevent acute rejection themselves have serious side effects that encourage close monitoring of blood glucose and cardiovascular function.[327] Because renal transplantation greatly increases the risk of infection, it is very important to consider invasive monitoring carefully and if indicated follow strict aseptic technique.

Drugs in Patients With Renal Failure

Patients with renal azotemia have a threefold or higher risk of having an adverse drug reaction than do patients with normal renal function.[328-330] The risk is increased by two conditions. First, excessive pharmacologic effects result from high levels of a drug or its metabolite (e.g., the metabolite of meperidine) in blood because of physiologic changes in target tissues induced by the uremic state. An example is excessive sedation in a uremic patient with standard blood levels of sedative-hypnotic drugs. Second, excessive administration of electrolytes with drugs also increases the risk of having an adverse drug reaction. Administration of standard doses of drugs that depend on renal excretion for their elimination can result in drug accumulation and enhanced pharmacologic effect. In one report, patients with end-stage renal disease required significantly higher propofol doses to achieve the clinical endpoint of hypnosis than did patients with normal renal function.[330]

INFECTIOUS DISEASE

Sepsis is a leading cause of postoperative morbidity,[317,331] probably through a decrease in systemic vascular resistance related to activation of the complement system and other mediators. Thus attention to the effects of antibiotic drugs must be supplemented by attention to intravascular volume status.[315-317,331-333] The degree of impairment of the infected organ and its effect on anesthesia should be assessed. Further, note that not all sepsis is the same, and often the source requires special consideration. For instance, endocarditis merits examination of the following: intravascular volume status; antibiotic and other drug therapy and side effects[334]; myocardial function; and renal, pulmonary, neurologic, and hepatic function—organ systems that can be affected by endocarditis.

Although all surgery except emergency or essential operations is proscribed when an acute infectious disease is present, many such diseases (e.g., influenza and pneumococcal pneumonia) and even inflammatory conditions are becoming less frequent because of successful immunization recommendations and programs.[335] Furthermore, even though acute infections are less common, surgery in patients with chronic viral diseases such as hepatitis and HIV infection is more frequent. Many of these patients may also harbor opportunistic infections such as tuberculosis or may have other systemic problems. Whether anesthesia or surgery, or both, exacerbates these infections or their systemic manifestations is not clear.

ELECTROLYTE DISORDERS

Disorders of calcium, magnesium, and phosphate balance are discussed in the earlier section on diseases involving the endocrine system and disorders of nutrition.

Hyponatremia and Hypernatremia

Electrolyte disorders are usually detected by determining the levels of electrolytes in serum. These concentrations reflect the balance between water and electrolytes. The osmolality of all body fluids is normally maintained within the narrow physiologic range of 285 to 295 mOsm/kg H_2O by integration of three key processes: thirst, release of ADH, and responsiveness of the medullary collecting ducts to ADH. Because of the permeability of biologic membranes, intracellular osmolality and extracellular osmolality are almost always equal.

$$2\left[\mathrm{Na}^{2+}\right](\mathrm{mEq/L}) + \frac{[\mathrm{Glucose}]\,(\mathrm{mg/dL})}{18} + \frac{[\mathrm{BUN}]\,(\mathrm{mg/dL})}{2.8} = \mathrm{mOsm/kg}$$

Hyponatremia is the most common electrolyte disorder in hospitalized patients, with a prevalence in ICUs patients as high as 40%, highlighting hyponatremia as a common and important clinical condition that adds complexity to the care.[335a] Hyponatremia can occur in isotonic, hypertonic, or hypotonic forms. For example, isotonic hyponatremia can develop in protein or liquid accumulation states such as myeloma. Hypertonic hyponatremia can be present with hyperglycemia or with infusions of glycine (as in the TURP syndrome). Hypotonic hyponatremia is the largest classification and is subdivided according to the status of the extracellular fluid into hypovolemic, isovolumic, or hypervolemic hypotonic hyponatremia. All three types require that excretion of renal water be impaired despite continued intake of dilute fluid. Common causes of hypovolemic

BOX 32.5 Types and Causes of Hypotonic Hyponatremia

Hypovolemic

- Gastrointestinal losses
  - Vomiting
  - Diarrhea
- Skin losses
- Third-space losses
- Lung losses
- Renal losses
  - Diuretics
  - Renal damage
  - Urinary tract obstruction
- Adrenal insufficiency

Isovolumic

- Syndrome of inappropriate secretion of antidiuretic hormone
- Renal failure
- Water intoxication
- Hypokalemia
- Dysfunctional osmostat

Hypervolemic

- Congestive heart failure
- Nephrosis
- Liver dysfunction

Serum osmolality less than 280 mOsm/L.

hypotonic hyponatremia are GI losses (vomiting, diarrhea), third-space losses (diuretics or salt-wasting nephropathy), and adrenal insufficiency (Box 32.5). Hypervolemic hypotonic hyponatremic states complicate severe cardiac failure, cirrhosis, nephrotic syndrome, and renal failure, and are characterized by retention of sodium with disproportionately larger amounts of water.

The most common isovolumic hypotonic hyponatremia is caused by retention of water without sodium, often edema is not usually clinically apparent. Edema is most often caused by SIADH, which in turn may be caused by CNS or pulmonary tumors or dysfunction. Secretion of ADH increases with age, thus rendering older adults more prone to hyponatremia. Drugs that potentiate the secretion of ADH (tricyclic antidepressants and vincristine) or its effects on the medullary collecting duct system in the kidney (nonsteroidal antiinflammatory drugs and thiazides) or that have similar effects (oxytocin and desmopressin) may be more likely to cause hyponatremia in older adults. To establish the diagnosis of SIADH, the physician should determine that the patient is free of renal and cardiac dysfunction, has normal adrenal and thyroid function, and is normovolemic—it is a diagnosis of exclusion. Urine osmolality would then be found to exceed 100 mOsm/kg, serum osmolality would be low, and urine sodium excretion would be higher than 20 mEq/L (20 mOsm/L).

Disturbances in serum sodium therefore may reflect alterations in glucose metabolism, renal function, or accumulation of body water. The last can be affected by disturbances in thirst, release of ADH, and renal function. Thus hyponatremia reflects a relative excess of free water and can occur when total-body sodium increases (as in edematous disorders), when total-body sodium is normal (as in excess of free water because of SIADH), or when total-body sodium decreases (as occurs with too aggressive use of diuretic drugs). Definition of the cause defines the treatment. For instance, water restriction is the mainstay of therapy for SIADH. Administration of demeclocycline is another option that corrects severe SIADH by inducing a reversible nephrogenic diabetes insipidus. The anesthesiologist is faced with the question of which levels of electrolytes require treatment before anesthesia. Although slowly developing hyponatremia usually produces few symptoms, the patient may be lethargic, apathetic, or unbalanced. Chronic hyponatremia is better tolerated than acute hyponatremia because of mechanisms regulating intracellular fluid volume that alleviate brain edema; the loss of other solutes from cells decreases the osmotic movement of water into cells. Nonetheless, severe chronic hyponatremia (i.e., serum sodium levels <123 mEq/L) can cause the development of brain edema.

By contrast, acute hyponatremia may be manifested by severe symptoms requiring emergency treatment: profound cerebral edema with obtundation, coma, convulsions, and disordered reflexes and thermoregulatory control.[100,101,336] Depending on the cause and relative total sodium and water content, treatment can range from the administration of hypertonic saline (with or without diuretic drugs) to restriction of fluids or administration of other drugs.[100,101,336] Because neurologic damage may develop if the serum sodium concentration is increased too rapidly, the rate of increase should not exceed 1 mEq/L/h.[100,101,336] After the serum sodium concentration has reached 125 mEq/L, therapy may consist of water restriction; more rapid correction may result in the osmotic demyelination syndrome.[335a] In hyponatremic patients who have excess total-body water secondary to SIADH, serum levels can be corrected by giving furosemide and saline to replace the loss of electrolytes in urine.[100,101,336] The diagnosis of SIADH is discussed earlier in this chapter (see the section on pituitary abnormalities).

Neither acute nor chronic hyponatremia necessitates restoration of serum sodium to normal levels, just until resolution of neurologic symptoms; brain swelling usually resolves at a serum sodium level of 130 mEq/L.

Hypernatremia occurs much less commonly than hyponatremia. It is often iatrogenic (e.g., it can be caused by failure to provide sufficient free water to a patient who is unconscious or who has had a recent stroke-induced deficit of the thirst mechanism) and can occur in the presence of low, normal, or excess total-body sodium. The primary symptoms of hypernatremia relate to brain cell shrinkage. Because too rapid correction of hypernatremia can lead to cerebral edema and possibly osmotic demyelination syndrome with convulsions, coma, and death; correction should be made gradually. Despite lack of data, there is general belief that all patients undergoing surgical procedures should have serum sodium concentrations of less than 150 mEq/L before anesthesia unless a therapeutic for hypernatremia exists (i.e., hypertonic therapy for cerebral edema in neurologic injury).

Hypokalemia and Hyperkalemia

Hypokalemia and hyperkalemia are also discussed in Chapters 31 and 47. The relationship between the measured potassium concentration in serum and total-body potassium stores can best be described with a scattergram. Only 2% of total-body potassium is stored in plasma (4200 mEq in cells and 60 mEq in extracellular fluid). In normal persons, 75% of the 50 to 60 mEq/L of total-body potassium is stored in skeletal muscle, 6% in red blood cells, and 5% in the liver. Thus a 20% to 25% change in potassium levels in plasma could represent a change in total-body potassium of 1000 mEq or more if the change were chronic or as little as 10 to 20 mEq if the change were acute.

As with serum sodium levels, acute changes in serum potassium levels are less well tolerated than chronic changes. Chronic changes are relatively well tolerated because of the equilibration of serum and intracellular stores that takes place over time to return the resting membrane potential of excitable cells to nearly normal levels.

Hyperkalemia can result from the following: factitious increase of potassium administration (as in red blood cell hemolysis); excessive exogenous potassium from sources such as salt substitutes; cellular shifts in potassium (as a result of metabolic acidosis, tissue and muscle damage after burns, use of depolarizing muscle relaxants, or intense catabolism of protein); and decreased renal excretion (as occurs in renal failure, renal insufficiency with trauma, and therapy with potassium-sparing diuretic drugs, especially when combined with ACE inhibitors or mineralocorticoid deficiency).[337-339] Factitious hyperkalemia can occur when a tourniquet is left on too long or even by simple fist clenching.[340]

The major danger in anesthetizing patients who have disorders of potassium balance appears to be abnormal cardiac function (i.e., both electrical disturbances and poor cardiac contractility).[337] Hyperkalemia lowers the resting membrane potential of excitable cardiac cells and decreases the duration of the myocardial action potential and upstroke velocity. This decreased rate of ventricular depolarization, in addition to the beginning of repolarization in some areas of the myocardium while other areas are still undergoing depolarization, produces a progressively widening QRS complex that merges with the T wave into a sine wave on the ECG.

At a potassium level greater than 6.7 mEq/L, the degree of hyperkalemia and the duration of the QRS complex correlate well.[337] This correlation is even better than the correlation between the serum potassium level and T-wave changes. Nevertheless, the earliest manifestations of hyperkalemia are narrowing and peaking of the T wave. Although not diagnostic of hyperkalemia, T waves are almost invariably peaked and narrow when serum potassium levels are 7 to 9 mEq/L. When serum potassium levels exceed 7 mEq/L, atrial conduction disturbances appear, as manifested by a decrease in P-wave amplitude and an increase in the PR interval. Supraventricular tachycardia, atrial fibrillation, PVCs, ventricular tachycardia, ventricular fibrillation, or sinus arrest may all occur.

The ECG and cardiac alterations associated with hyperkalemia are potentiated by low serum levels of calcium and sodium. Intravenous administration of bicarbonate, glucose with insulin (1 unit/2 g glucose), can reverse these changes temporarily by shifting extracellular potassium into the cells. Calcium is administered to stabilize the cardiac membrane; it has no effect on plasma concentrations of potassium. Furosemide should be given to start the removal process of excess potassium from the body and decrease serum potassium levels. Sodium polystyrene sulfonate (Kayexalate) enemas can be given to bind potassium in the gut in exchange for sodium, these should be used with caution in perioperative patients as there are reports of intestinal necrosis.[340a,340b] Dialysis against a hypokalemic solution also decreases serum potassium levels.

β-Adrenergic stimuli also cause redistribution of potassium into the cell. Indeed, the plasma potassium concentration measured in samples immediately before surgical procedures is usually 0.2 to 0.8 mEq/L lower than that measured during the less stressful period 1 to 3 days before surgery.[341] β-Adrenergic receptor blocking drugs can be used to prevent such an effect preoperatively. A β-adrenergic receptor stimulating agent (20 mg of nebulized albuterol for a 70-kg patient) can be used to treat hyperkalemia when it occurs; it decreases potassium levels 1.0 mEq/L within 30 minutes, and its effect lasts 2 hours.[342] Although nebulized β_2-agonists effectively lower plasma potassium concentrations by stimulating sodium- and potassium-dependent adenosine triphosphatase, this therapy should be used as an adjunct to rather than a substitute for more established measures.

In a hyperkalemic patient, hypoventilation can be dangerous during anesthesia because each 0.1 change in pH can produce a 0.4 to 1.5 mEq/L change in serum potassium levels in the opposite direction. For example, if pH decreases from 7.4 to 7.3, serum potassium levels could increase from 5.5 to 6.5 mEq/L.

Hypokalemia can be caused by inadequate intake of potassium, excessive GI loss (through diarrhea, vomiting, nasopharyngeal suctioning, long-term use of laxatives, or ingestion of cation exchange resins, as in certain wines), excessive renal loss (because of the use of diuretic drugs, renal tubular acidosis, chronic chloride deficiency, metabolic alkalosis, mineralocorticoid excess, excessive ingestion of licorice, use of antibiotics, ureterosigmoidostomy, and diabetic ketoacidosis), and shifts of potassium from extracellular to intracellular compartments (as occurs in alkalosis, insulin administration, administration of a β-adrenergic agonist, stress, barium poisoning, and periodic paralysis). As with hyperkalemia, knowledge of the cause of the potassium deficiency and appropriate preoperative evaluation and treatment of that cause may be as important as treatment of the deficiency itself. Also like hyperkalemia, hypokalemia may reflect small or vast changes in total-body potassium. Acute hypokalemia may be much less well tolerated than chronic hypokalemia. The major worrisome manifestations of hypokalemia pertain to the circulatory system, both the cardiac and peripheral components. In addition, chronic hypokalemia results in muscle weakness, hypoperistalsis, and nephropathy.

Cardiovascular manifestations of hypokalemia include the following: autonomic neuropathy, orthostatic hypotension, decreased sympathetic reserve, impaired myocardial contractility, and electrical conduction abnormalities. Conduction abnormalities can present as sinus tachycardia, atrial and ventricular arrhythmias, and intraventricular conduction disturbances that can progress to ventricular fibrillation. In addition to arrhythmias, the ECG shows widening of the QRS complex, ST-segment abnormalities, progressive diminution of the T-wave amplitude, and a progressive increase in the U-wave amplitude. Surawicz found these changes to be invariably present when serum potassium levels decreased to less than 2.3 mEq/L.[337] Although U waves are not specific for hypokalemia, they are sensitive indicators of the condition. Replenishing the total-body potassium deficit for a depletion reflected by a serum deficit of 1 mEq/L (e.g., from 3.3 to 4.3 mEq/L) may require 1000 mEq of potassium. Even if this amount could be given instantaneously (and it should not be replenished at a rate exceeding 250 mEq/day), it would take 24 to 48 hours to equilibrate in all tissues. Potassium-depleted myocardium is unusually sensitive to digoxin, calcium, and most important, potassium. Rapid potassium infusion in a hypokalemic patient can produce arrhythmias as severe as those produced by hypokalemia itself, again, slow correction is preferred.[343]

Thus the decision to proceed with surgery and anesthesia in the presence of acute or chronic depletions or excesses of potassium depends on many factors.[344-349] The cause and treatment of the underlying condition creating the electrolyte imbalance and the effect of that imbalance on perioperative risk and physiologic processes must be known. The urgency of the operation, the degree of electrolyte abnormality, the medications given, the acid-base balance, and the suddenness or persistence of the electrolyte disturbance are all considerations. For example, a small study of patients undergoing vascular access procedures with preoperative potassium levels of higher than 6 mmol/L demonstrated no adverse outcomes.[347] Similarly, in a cohort study in which 38 patients had a preoperative potassium level higher than 5.5 mEq/L, no dysrhythmias or major morbidity were associated with the use of succinylcholine.[348]

Retrospective epidemiologic studies attribute significant risk to the administration of potassium (even long-term oral administration).[344] In one study, 1910 of 16,048 consecutive hospitalized patients were given oral potassium supplements. Of these 1910 patients, hyperkalemia contributed to death in 7, and the incidence of complications of potassium therapy was 1 in 250.[350] Armed with such data, many internists do not prescribe oral potassium therapy for patients given diuretic drugs, yet these patients frequently become moderately hypokalemic.[350] Modest hypokalemia occurs in 10% to 50% of patients given diuretic drugs.

Three studies investigated whether modest hypokalemia was a problem by prospectively seeking arrhythmias on the ECGs of patients who had various preoperative levels of potassium.[345,346,349] No difference in the incidence of arrhythmias occurred in 25 normokalemic (K^+ >3.4 mEq/L) patients, 25 moderately hypokalemic (K^+ = 3-3.4 mEq/L) patients, and 10 severely hypokalemic (K^+ < 2.9 mEq/L) patients.[345] Wahr and coauthors studied 2402 patients undergoing elective CABG and concluded that a serum potassium level less than 3.5 mmol/L was a predictor of perioperative arrhythmia (OR, 2.2; 95% CI, 1.2-4.0), intraoperative arrhythmia (OR, 2.0; 95% CI, 1.0-3.6), and postoperative atrial fibrillation/flutter (OR, 1.7; 95% CI, 1.0-2.7).[349]

Modest hypokalemia can have severe consequences.[350,351] Holland and coworkers treated 21 patients with 50 mg of hydrochlorothiazide twice a day for 4 weeks.[351] These patients had a history of becoming hypokalemic during diuretic therapy; no patients had cardiac disease or were taking other medications. Before and after diuretic therapy, 24-hour ambulatory ECGs were recorded. This study is also subject to the limitations of Holter monitoring. Ventricular ectopy, including complex ventricular ectopy (multifocal PVCs, ventricular couplets, ventricular tachycardia), developed in 7 of the 21 patients (33%). Potassium repletion decreased the number of ectopic ventricular beats per patient from 71.2 to 5.4/h. Apparently, some patients are sensitive to even minor potassium depletion. In the Multiple Risk Factor Intervention Trial involving 361,662 patients, more than 2000 of whom were treated for hypertension with diuretics, the reduction in serum potassium after diuretic therapy was greater in patients with PVCs.[350]

Gastrointestinal and Liver Diseases

GASTROINTESTINAL DISEASE

Preoperative Search for Diverse Associated Disorders in Gastrointestinal Disease

Although preoperative preparation of the GI tract is usually the responsibility of the surgeon, GI disease can and often does cause derangements in many or all other systems. Such disturbances can affect the safety of anesthesia for the patient. Preoperative preparation should include knowledge of disease processes and their effects to guide the patient smoothly through the perioperative period. The major advances of correcting fluid and electrolyte disorders and optimizing nutritional status preoperatively allow surgical procedures to be performed in patients with GI disease previously deemed to be at too great a risk and may have lessened the risk for others.[45-47,352] Nonetheless, in patients with GI disease, thorough assessment of intravascular fluid volume, electrolyte concentrations, and nutrition is essential, including an evaluation of the supervening side effects of these therapies (e.g., hypophosphatemia from parenteral nutrition, hyperkalemia or cardiac arrhythmias from too vigorous treatment of hypokalemia, and volume overload from too rapid or too vigorous treatment of hypovolemia).

In addition to the vast alterations in fluids, electrolytes, and nutrition that can occur with such diverse GI diseases as neoplasms and pancreatitis, patients with GI disorders can have gastroesophageal reflux disease,[353] bowel obstruction, vomiting, or hypersecretion of acid. These effects may merit rapid induction of anesthesia with the application of cricoid pressure or endotracheal intubation with the patient unanesthetized (awake), preoperative nasogastric suctioning, or preoperative use of histamine receptor blocking drugs. Clotting abnormalities may need to be corrected because fat-soluble vitamin K (often malabsorbed) is necessary for the synthesis of factors II, VII, IX, and X in the liver. Liver disease is often associated with GI disease and, if severe enough, can also result in a deficiency of clotting factors synthesized by the liver.

Other factors should be remembered in the perioperative management of any patient with GI disease. First, closed spaces containing gas expand by absorbing nitrous oxide, as such expansion can lead to ischemic injury, rupture of GI viscera, or both. Second, GI surgery predisposes the patient to blood stream contamination, which can lead to sepsis and decreased peripheral vascular resistance, massive fluid requirements, cardiac failure, and renal insufficiency. The surgical site infection rate has been declining. This decrease may be attributable to the use of better technique, more appropriate prophylactic timing and use of antibiotics, better nutrition, less invasive (laparoscopic and endoscopic) surgery, maintenance of normothermia, and surgical resection of even tumors.[354-358] Third, patients with GI disease may have many other associated disorders not directly related to the GI tract. For example, they may be anemic from deficiencies in iron, intrinsic factor, folate, or vitamin B_{12}.

They may also manifest neurologic changes from combined-system disease. Respiration may be impaired because of tobacco abuse, peritonitis, abscess, pulmonary obstruction, previous incisions, aspiration, or pulmonary embolism (as occurs with ulcerative colitis or with thrombophlebitis in bedridden patients). These patients may also have hepatitis, cholangitis, side effects from antibiotic drugs or other medications, massive bleeding with anemia and shock, or psychological derangements.

Because GI disease can be accompanied by so many diverse associated disorders, the clinician must clearly search for involvement of other systems and preoperatively assess and treat such disorders appropriately. Discussion of two specific diseases, ulcerative colitis and carcinoid tumor, highlights the importance of involvement of other systems in GI disease.

Ulcerative Colitis and Carcinoid Tumors as Examples of Gastrointestinal Disease Affecting Other Systems

Ulcerative colitis is a chronic inflammatory disease of the colonic mucosa, typically starting in the rectum and extending proximally through the colon. It is often marked with an unpredictable clinical course with periods of remission and exacerbation. Patients with ulcerative colitis may also have the following: phlebitis; deficiencies in iron, folate, or vitamin B_{12}; anemia; or clotting disorders caused by malabsorption. They can present as malnourished or dehydrated, or with electrolyte abnormalities. In addition, ulcerative colitis can be accompanied by massive bleeding, bowel obstruction, bowel perforation, toxic megacolon, hepatitis, arthritis, iritis, spondylitis, diabetes, or pancreatitis.

The site of origin of carcinoid tumors in more than 60% of patients is the GI tract.[358a] Within the GI tract, carcinoid tumors have been documented to occur from the esophagus to the rectum. Tumors arising in the ileocecal region have the highest incidence of metastases. Carcinoid tumors originating from sites other than the GI tract, such as the head and neck, lung, gonads, thymus, breast, and urinary tract, have also been reported. Cardiac involvement, although frequently reported, is usually limited to right-sided valvular and myocardial plaque formation.[359]

Not all patients with carcinoid tumors have symptoms attributable to secretion of hormone by the tumor. Some do, however, and unexpected carcinoid can manifest intraoperatively by hypersecretion of gastric fluid. The most comprehensive series in the literature indicates that only 7% of patients have carcinoid syndrome, which typically consists of flushing, diarrhea, and valvular heart disease. Of those patients with the syndrome, approximately 74% have cutaneous flushing, 68% have intestinal hypermotility, 41% have cardiac symptoms, and 18% have wheezing. Factors influencing symptoms include the location of the tumor and the specific hormones produced and secreted. Although it is generally believed that if patients do not exhibit carcinoid syndrome, the tumors are not producing serotonin (5-hydroxytryptamine [5-HT]), such may not be the case. Approximately 50% of patients with carcinoid tumors of the GI tract demonstrate evidence of 5-HT production as manifested by elevated urinary levels of 5-hydroxyindoleacetic acid (5-HIAA), a metabolic product of 5-HT. Carcinoid syndrome is usually associated with ileal carcinoid tumors that have metastasized to the liver. Presumably, the liver clears mediators released from the tumor. Impairment of this clearing ability by the metastatic tumor results in carcinoid syndrome.

Most patients with carcinoid tumors and increased urinary 5-HIAA levels have typical carcinoid tumors originating from the midgut (ileum or jejunum). These patients excrete only small amounts of 5-hydroxytryptophan (5-HTP). Patients with atypical carcinoid tumors that originate in the foregut (bronchus, stomach, and pancreas) excrete large amounts of 5-HT and 5-HTP, as well as moderately higher amounts of 5-HIAA.

Although it is generally agreed that 5-HT is responsible for the diarrhea experienced by patients with carcinoid tumors, other neurohumoral agents may contribute to the flushing and hypotension, including dopamine, histamine, and some of the neuropeptides such as substance P, neurotensin, vasoactive intestinal peptide, and somatostatin.

The net physiologic effect of circulating 5-HT represents a composite of both direct action (mediated by 5-HT receptors) and indirect action (mediated through modulation of adrenergic neurotransmission). The existence of several subtypes of 5-HT receptors may account for the different effects of 5-HT on various serotonin-sensitive tissue beds. Indirect actions are effected through alterations in catecholamine release and depend on the level of circulating 5-HT.

5-HT has little, if any, direct effect on the heart. With increased levels, however, positive chronotropic and inotropic myocardial effects may occur, mediated by the release of noradrenaline (norepinephrine). Effects of serotonin on the vasculature include both vasoconstriction and vasodilation.

Alterations in GI function attributed to 5-HT include increased motility and net intestinal secretion of water, sodium chloride, and potassium. 5-HT reportedly causes bronchoconstriction in many animals, but rarely in humans. Patients with asthma are a possible exception. Carcinoid tumors frequently manifest as diarrhea with fluid and electrolyte abnormalities. Because these tumors secrete vasoactive substances, patients can exhibit hypotension or hypertension along with the flush associated with release of vasoactive substances. Vasoactive substances can be released from the tumor by any number of substances, including catecholamines. The anesthesiologist needs to be ready and able to treat hypotension, decreased peripheral vascular resistance, bronchospasm, and hypertension. This difficulty in managing carcinoid syndrome seemed to change with the availability of a somatostatin analogue, octreotide, and lanreotide. In fact, somatostatin is such a powerful inhibitor of the release of peptides from carcinoid tumors and an inhibitor of the peptic effects on receptor cells that it is the therapy of choice for preoperative, intraoperative, and postoperative management of carcinoid symptoms and crises.[360,361] In cardiac surgical patients, mortality has declined over time, and vasopressors have been shown to be safe in conjunction with octreotide.[362] However, the ease of management of most patients[360,361,363-366] should not lull the anesthesiologist into being unprepared—in fact, somatostatin has caused problems of its own and has failed to prevent severe hypotension and bronchospasm.[367,368]

In patients with severe hypotension that is not treatable with somatostatin, the drug of choice is vasopressin; angiotensin has demonstrated benefit but only recently become available in the United States. However, the vasoactive substances released by carcinoid tumors cause fibrosis of the heart valves that often results in pulmonic stenosis or tricuspid insufficiency. To increase cardiac output in a patient with tricuspid insufficiency, the anesthesiologist should avoid drugs or situations that increase pulmonary vascular resistance. In addition, the production of large amounts of 5-HT (equal to 200 mg/day of 5-HIAA) can lead to the development of niacin deficiency with pellagra (as occurs with diarrhea, dermatitis, and dementia).

Steroids have been effective in treating the symptoms of bronchial carcinoid tumors. Although prophylactic preoperative administration and intraoperative therapeutic use have been described, controlled studies of beneficial effects are lacking. Aprotinin, like steroids, inhibits the kallikrein cascade by blocking the proteinase activity of kallikrein, and some reports have described a dramatic clinical response, though it is not available in the United States.

A subset of patients with symptoms of carcinoid syndrome excretes histamine at increased levels in their urine. Histamine causes vasodilation of small blood vessels, which leads to flushing and decreased total peripheral resistance. Histamine is known to cause bronchoconstriction, particularly in patients with bronchial asthma and other pulmonary diseases. Histamine receptor blocking drugs have been used with some success in alleviating the flushing associated with carcinoid syndrome. H_2 antagonism alone was found to be just as effective as combination therapy in preventing symptoms; pure H_1 antagonism, however, was ineffective. These therapies have been relegated to a second-line defense since the use of somatostatin.

Catecholamines aggravate the symptoms of carcinoid syndrome, presumably by stimulating release of hormone by the tumor. Adrenergic receptors have not been demonstrated in carcinoid tumors, nor do these tumors usually have neural innervation. Perhaps adrenergic stimuli work through their mechanical effects on the gut and vessels to stimulate the release of tumor products. Treatment of patients with carcinoid tumors by means of α- and β-adrenergic antagonists has been beneficial in ameliorating flushing in some instances but ineffective in others.

The results of prospective studies on somatostatin to ameliorate the symptoms of carcinoid syndrome have been dramatic. Somatostatin appears to have been a major advance in the treatment of carcinoid syndrome, it is now the mainstay of medical treatment perioperatively.

Bronchospasm with or without flushing also develops in many patients when vasoactive substances are released. Thus a patient with a carcinoid tumor may be well or may be severely incapacitated by pulmonary, neurologic, nutritional, fluid, electrolytic, or cardiovascular disturbances.

Therefore, although the GI system in itself may not require extensive preoperative preparation, GI disease can cause disturbances in any or all other systems that require extensive preoperative preparation to optimize the patient's condition in addition to preoperative knowledge of physiology and the effects of diseases to guide patients through the perioperative period smoothly. In addition, the anesthesiologist's understanding of the nature of the surgical procedure aids in determining the system involvement caused by the GI disorder.

Another perioperative consideration is that patients with GI diseases have had to endure the psychosocial trauma of having to live with their disease for long periods or the necessity of facing such a prospect.[369] They need emotional support, kindness, and empathy as much as, if not more than, other patients without sacrificing scientific rigor in the treatment of their condition. Obtaining relevant psychological data while gathering medical information, sitting while taking the history, and empathizing with the patient about how difficult it must be to accomplish tasks with this disease legitimize the physician's interests in and support of the patient's pain and other psychosocial issues. The time spent sitting and talking with the patient also allows the anesthesiologist to discuss options for pain therapy with the patient, and other issues that show the anesthesiologist to be both a competent physician and particularly concerned with that patient's well-being.

LIVER DISEASE

What are the risks of giving anesthesia to patients with acute liver disease who require emergency surgery? What are the risks of giving anesthesia to patients with chronic impairment of liver function? What can be done to minimize these risks? Although one may think that the experiences gained from providing anesthesia for liver transplantation would answer many of these questions, a substantial difference exists between optimizing cardiovascular function to meet the needs of a new liver (e.g., supply of nutrients) and maintaining liver function in a diseased liver. Hepatic physiology and pathology are discussed in Chapter 16.

Hematologic Disorders and Oncologic Disease

HEMATOLOGIC DISORDERS

Sickle Cell Anemia and Related Hemoglobinopathies

The sickle cell syndromes constitute a family of hemoglobinopathies caused by abnormal genetic transformation of amino acids in the heme portion of the hemoglobin molecule. The sickle cell syndromes arise from a mutation in the β-globin gene that changes the sixth amino acid from valine to glutamic acid. A major pathologic feature of sickle cell disease is the aggregation of irreversibly sickled cells in blood vessels. The molecular basis of sickling is the aggregation of deoxygenated hemoglobin B molecules along their longitudinal axis.[370] This abnormal aggregation distorts the cell membrane and thereby produces a sickle shape. Irreversibly sickled cells become dehydrated and rigid and can cause tissue infarcts by impeding blood flow and oxygen to tissues.[370-373] Several studies show enhanced adhesion of sickled erythrocytes to vascular endothelium, as well.[374] Some other abnormal hemoglobins interact with hemoglobin S to various degrees and give rise to symptomatic disease in patients heterozygous for hemoglobin S and one of the other hemoglobins such as the hemoglobin of thalassemia (hemoglobin C).

Three tenths of 1% of the African American population in the United States have sickle cell-thalassemia disease (hemoglobin SC); these patients also have end-organ disease and symptoms suggestive of organ infarction. For these patients, perioperative considerations should be similar to those for patients with sickle cell disease (hemoglobin SS).

Whereas 8% to 10% of African Americans have the sickle cell trait (hemoglobin AS), 0.2% are homozygous for sickle cell hemoglobin and have sickle cell anemia. Sickle cell trait is a heterozygous condition in which the individual has one βS globin gene and one βA globin gene, which results in the production of both hemoglobin S and hemoglobin A, with a predominance of hemoglobin A. Sickle cell trait is not clinically significant because hemoglobin AS cells begin to sickle only when the oxygen saturation of hemoglobin is less than 20%. Minimal difference has been found between physiologically normal persons (i.e., those with hemoglobin AA) and those with hemoglobin AS regarding survival rates, though there is one exception—patients with hemoglobin AS have a 50% increase in pulmonary infarction. However, single case reports of a perioperative death and a perioperative brain infarct in two patients with hemoglobin AS disease do exist, as does a report of death believed to be caused by aortocaval compression during general anesthesia that resulted in a sickling crisis.[375] Frequent measurement of oxygen saturation (pulse oximetry) in multiple areas of the body is recommended when caring these AS patients, including the ear and toe in pregnant patients.[375]

The pathologic end-organ damage that occurs in sickle cell states is attributable to three processes: the sickling or adhesion of cells in blood vessels, which causes infarcts and subsequent tissue destruction secondary to tissue ischemia; hemolytic crisis secondary to hemolysis; and aplastic crises that occur with bone marrow exhaustion, which can rapidly result in severe anemia. Patients currently in crisis should not undergo surgery except for emergencies, and then only after an exchange transfusion.[372,374-378]

Because sickling is increased with lowered oxygen tensions, acidosis, hypothermia, and the presence of more desaturated hemoglobin S; current therapy includes keeping the patient warm and well hydrated, giving supplemental oxygen, maintaining high cardiac output, and avoiding areas of stasis with pressure or tourniquets. Meticulous attention to these practices in periods when we do not usually pay most careful attention (i.e., waiting in the preinduction area) or when gas exchange may be most unmatched to the cardiovascular-metabolic demands (early postoperative period) may be important in lessening morbidity. Following these measures routinely succeeded in reducing mortality to 1% in several series of patients with sickle cell syndromes.[375,378,379] Retrospective review of patients' charts led the authors of those studies to conclude that, at most, a 0.5% mortality rate could be attributed to the interaction between sickle cell anemia and anesthesia.

Several investigators have advocated using partial exchange transfusions perioperatively. In children with sickle cell anemia and acute lung syndromes, partial exchange transfusion improved clinical symptoms and blood oxygenation. In addition, serum bilirubin levels decreased in patients with acute liver injury. Clinical improvement of pneumococcal meningitis and cessation of hematuria in papillary necrosis also accompanied exchange transfusion.[371] The goal of transfusion therapy is to lower the concentration of hemoglobin S to less than 30%, minimize splenic sequestration, treat severe anemia, and avoid acute chest syndrome due to low PaO_2.[379a] Exchange transfusion serves to lower the concentration of hemoglobin S, while red blood cell transfusions serve to correct anemia. To date only regular transfusion therapy has been associated with improved mortality in the extended period.[379b,c] Two studies demonstrated a possible decrease in perioperative morbidity after partial exchange transfusion when compared with the risks of exchange transfusion.[373,380] A retrospective review of 14 patients with sickle cell anemia who were undergoing total hip revision supported the decision to perform a simple transfusion preoperatively only if the patient's hemoglobin is significantly lower than their steady-state hemoglobin level.[381] Transfusion can be used intraoperatively according to hemoglobin level or blood loss volume. Other conditions are common in sickle cell syndromes: pulmonary dysfunction with increased shunting, renal insufficiency, gallstones, small MIs, priapism, stroke, aseptic necrosis of bones and joints, ischemic ulcers, retinal detachment as a result of neovascularization, and complications of repeated transfusions.

In thalassemia, globin structures are normal, but because of gene deletion, the rate of synthesis of either the α or β chains of hemoglobin (α- and β-thalassemia, respectively) decreases.[382-384] Two copies of the gene that codes for the α-globin chain are located on chromosome 16. Deletion of all four of these genes causes cell death in utero, and three deletions cause severe chronic hemolysis and a shortened life span. α-Thalassemia-1 (trait) occurs when two genes have been deleted and mild anemia results; α-thalassemia-2 (silent) occurs when the two genes have been deleted but no mild anemia or microcytosis results. In α-thalassemia trait, the hemoglobin A_2 level is normal. β-Thalassemia is associated with an excess of α chains, which denature developing erythrocytes, thereby leading to their premature death in marrow or to shortened survival in the circulation. An elevated hemoglobin A_2 level is the hallmark of β-thalassemia trait, a common cause of mild anemia and microcytosis. These syndromes are common in Southeast Asia, India, and the Middle East and in people of African descent.

In thalassemia, facial deformity from erythropoietin-stimulated ineffective erythropoiesis (ineffective because of a genetic inability to produce useful hemoglobin) was reported to make endotracheal intubation difficult.[382,383] The anemia associated with these syndromes often produces compensatory hyperplasia of the erythroid marrow, which in turn is associated with severe skeletal abnormalities.[382-384]

Cytoskeletal Anemias (Hereditary Spherocytosis and Elliptocytosis), Enzyme-Deficient Anemias, and Autoimmune Hemolytic Anemias

Congenital abnormalities of the erythrocyte membrane are becoming better understood. In elliptocytosis and hereditary spherocytosis, the membrane is more permeable to cations and is more susceptible to lipid loss when cell energy is depleted than is the membrane of a normal red blood cell. Both hereditary spherocytosis (present in 1 in 5000 people) and hereditary elliptocytosis are inherited as autosomal dominant traits. In both disorders, defects in the membrane are thought to result from a mutation of spectrin, a structural protein of the membrane cytoskeleton.[385] Although the therapeutic role of splenectomy in these diseases is not fully defined, in severe disease, splenectomy is known to improve the shortened life span of the red blood cell from 20-30 days to 40-70 days. Because splenectomy predisposes the patient to gram-positive septicemia (particularly pneumococcal), perhaps patients should be given pneumococcal vaccine preoperatively. No specific problems related to anesthesia have been reported for these disorders.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency (a gender-linked recessive trait) has been recognized as the most common enzymopathy worldwide, most often expressed in males, and in patients of African, Asian, Mediterranean, or Middle Eastern descent.[385a] Young cells have normal activity, but older cells are grossly deficient when compared with normal cells. A deficiency in G6PD results in hemolysis of the erythrocyte and the formation of Heinz bodies. Red blood cell hemolysis can also occur with intercurrent infections or after the administration of drugs that produce substances requiring G6PD for detoxification (e.g., methemoglobin, glutathione, and hydrogen peroxide). Drugs to be avoided are sulfa drugs, quinidine, prilocaine, lidocaine, antimalarial drugs, antipyretic drugs, nonnarcotic analgesics, vitamin K analogues, and perhaps sodium nitroprusside.

The autoimmune hemolytic anemias include cold antibody anemia, warm antibody anemia (idiopathic), and drug-induced anemia and occur from antibody mediate destruction of red blood cells.[386-388] Cold antibody hemolytic anemia is mediated by IgM or IgG antibodies, which at room temperature and lower temperatures cause red blood cells to clump. When these patients are given blood transfusions, the cells and all fluid infusions must be warm, and body temperature must be meticulously maintained at 37°C if hemolysis is to be prevented. Warm antibody (or idiopathic) hemolytic anemia is mediated by IgG and is a difficult management problem characterized by chronic anemia, the presence of antibodies active against red blood cells, a positive Coombs test, and difficulty crossmatching blood. For patients undergoing elective surgery, autologous transfusions, predeposit of blood with or without erythropoietin stimulation,[389] and blood from rare Rh-negative red blood cell donors or the patient's first-degree relatives (or both) can be used. In emergency situations, the possibility of autotransfusion, splenectomy, corticosteroid treatment, rituximab, cyclophosphamide, or azathioprine should be discussed with a hematologist knowledgeable in this area.[389a]

Drug-induced anemias have three mechanisms. In receptor-type hemolysis, a drug (e.g., penicillin) binds to the membrane of the red blood cell, and the complex stimulates the formation of an antibody against the complex. In "innocent bystander" hemolysis, a drug (e.g., quinidine, sulfonamide) binds to a plasma protein, thereby stimulating an antibody (IgM) that cross-reacts with an erythrocyte. In autoimmune hemolysis, the drug stimulates the production of an antibody (IgG) that cross-reacts with the erythrocyte. Drug-induced hemolytic anemias generally cease when therapy with the drug ends.

Granulocytopenia

Granulocyte mechanisms have undergone experimental elaboration since 2000, partly because of the molecular biologic revolution: in addition to erythropoietin, more than 14 hemolymphopoietic growth factors or cytokines have been characterized biochemically and cloned genetically. These growth factors interact with cell-surface receptors to produce their major actions (Table 32.14).[390] Use of the colony-stimulating factors has permitted more intense oncologic treatment. The few reports related to their perioperative effects detail the unfavorable adverse consequences that such therapies can have on gas exchange when adverse immunologic effects occur.[391]

In patients who have fewer than 500 granulocytes/mL of blood and established sepsis, the use of growth factor and granulocyte transfusion has been shown to prolong life.[392-394] Although bone marrow transplantation is being used increasingly, complications usually occur after transplantation, not on harvesting of cells. Abnormal results on pulmonary function testing before bone marrow transplantation seem to predict complications after transplantation, but not so strongly as to preclude transplantation.[395]

Platelet Disorders

Although inherited platelet disorders are rare, acquired disorders are quite common and affect at least 20% of all patients in medical and surgical ICUs, with infections and drug therapies being the leading causes.[396] Both acquired and inherited platelet conditions cause skin and mucosal bleeding, whereas defects in plasma coagulation produce deep tissue bleeding or delayed bleeding. Perioperative treatment of inherited platelet disorders (e.g., Glanzmann thrombasthenia, Bernard-Soulier syndrome, Hermansky-Pudlak syndrome) consists of platelet transfusions. EACA has been used successfully to decrease perioperative bleeding in thrombocytopenic patients. The much more common acquired disorders may respond to one of several therapies. Immune thrombocytopenias, such as those associated with lupus erythematosus, idiopathic thrombocytopenic purpura, uremia, hemolytic-uremic syndrome, platelet transfusions, heparin, and thrombocytosis, may respond to steroids, splenectomy, plateletpheresis, eradication of *Helicobacter pylori*, or alkylating agents, or may require platelet transfusions, plasma exchange, whole blood exchange, or transfusion; sometimes these disorders do not respond to anything.[179,397,398] Traditionally, splenectomy is performed when steroid therapy fails or reaches a dosage that poses unacceptable risks of toxicity. Immunoglobulin infusions and rituximab may induce desirable remissions in idiopathic thrombocytopenic purpura without splenectomy.

Thrombotic thrombocytopenic purpura is a rare immune-mediated thrombotic microangiopathic disorder caused by antibodies to ADAMTS 13 (A Disintegrin AND Metalloproteinase with a Thrombospondin type 1 motif, member 13) that, despite various therapies, still carries a high mortality rate.[398a] The current therapies of plasma exchange, corticosteroids, and rituximab have improved survival rates, though new therapies are under investigation.[398b] One uncontrolled study implies that the benefit lies not only in improvement of the hematologic picture but also in prevention of ARDS, a leading cause of death in these patients.[398] In that study, early institution of plasmapheresis improved oxygenation.

By far the largest number of platelet abnormalities consists of drug-related defects in the aggregation and release of platelets. Aspirin irreversibly acetylates platelet cyclooxygenase, the enzyme that converts arachidonic acid to prostaglandin endoperoxidases. Because cyclooxygenase is not regenerated in the circulation within the life span of the platelet and because this enzyme is essential for the aggregation of platelets, one aspirin tablet may affect platelet function for a week. All other drugs that inhibit platelet function (e.g., vitamin E, indomethacin, sulfinpyrazone, dipyridamole, tricyclic antidepressant drugs, phenothiazines, furosemide, steroids) do not inhibit cyclooxygenase function irreversibly; these drugs disturb platelet function for only 24 to 48 hours. If emergency surgery is needed before the customary 8-day period for platelet regeneration after aspirin therapy or if the 2-day period for other drugs has not elapsed, administration of 2 to 5 units of platelet concentrate will return platelet function

TABLE 32.14 Major Effects of Hemolymphopoietic Growth Factors and Cytokines

Cytokine	Other Names	Biologic Effects
Erythropoietin		Erythrocyte production
Interleukin-3 (IL-3)	Multicolony-stimulating factor Stem cell–activating factor Persisting cell-stimulating factor Hemopoietin-2	Stimulates proliferation and differentiation of granulocyte, macrophage, eosinophil, mast cell, megakaryocyte, and T- and B-cell lineage and early myeloid stem cells Interacts with erythropoietin to stimulate erythroid colony formation, stimulates proliferation of AML blasts, and stimulates histamine release by mast cells
Granulocyte colony-stimulating factor (G-CSF)	Differentiation factor MGI-2	Stimulates granulocyte lineage proliferation and differentiation Acts on early myeloid stem cells, especially in association with other factors; synergizes with IL-3 to stimulate megakaryocyte colony formation Increases neutrophil phagocytes and antibody-dependent cell-mediated cytotoxicity Releases neutrophils from bone marrow and is chemotactic for neutrophils and monocytes Enhances phagocytosis and antibody-dependent cell-mediated cytotoxicity and oxidative metabolism of neutrophils Stimulates monocyte killing of *Mycobacterium avium-intracellulare* and *Candida* species, tumoricidal activity of monocytes, antibody-dependent cell-mediated cytotoxicity, and expression of cell-surface proteins
Granulocyte-macrophage colony-stimulating factor (GM-CSF)		Stimulates granulocyte, macrophage, and megakaryocyte proliferation and differentiation, early myeloid stem cells, and—in the presence of erythropoietin—erythropoiesis Enhances the cytotoxic and phagocytic colony-stimulating factor activity of neutrophils against bacteria, yeast, parasites, and antibody-coated tumor cells Increases surface expression of neutrophil adhesion proteins and enhances eosinophil cytotoxicity, macrophage phagocytosis, and basophil histamine release Amplifies IL-2–stimulated T-cell proliferation and stimulates B-cell lines to proliferate
Colony-stimulating factor-1	Macrophage colony-stimulating factor	Stimulates predominantly macrophage-monocyte proliferation and differentiation with lesser effects on granulocytes Acts synergistically with other factors on earlier myeloid stem cells Stimulates macrophage phagocytosis, killing, migration, antitumor activity, and metabolism Stimulates secretion of plasminogen activator, G-CSF, interferon, IL-3, or tumor necrosis factor by peritoneal macrophages
Interleukin-1 (α and β)	Endogenous pyrogen Hemopoietin-1 Osteoclast-activating factor Lymphocyte-activating factor	Induces synthesis of acute-phase proteins by hepatocytes Activates resting T cells, cofactor for T- and B-cell proliferation Chemotactic for monocytes and neutrophils Induces production of growth factors, including G-CSF, GM-CSF, IL-6, CSF-1, IL-3, and interferon by many cells Radioprotective in mice
Interleukin-2	T-cell growth factor	Growth factor for T cells, activates cytotoxic T lymphocytes, promotes synthesis of other cytokines, enhances natural killer cell function
Interleukin-4	B-cell–stimulating factor-1 (BSF-1) B-cell differentiation factor (BCDF) IgG induction factor	Enhances antibody production (IgG and IgE) and up-regulates class II MHC molecules and Fc receptors on B cells Costimulant with anti-IgM antibodies for induction of DNA synthesis in resting B cells Stimulates growth of activated T cells In the presence of IL-3, enhances mast cell growth; with G-CSF, enhances granulocytes of GM colony formation; and with erythropoietin and/or IL-1, stimulates erythroid and megakaryocyte colony formation
Interleukin-5	Eosinophil differentiation factor (EDF) T-cell–replacing factor (TRF) B-cell growth factor-II (BCGF-II) B-cell differentiation factor (BCDF)	Enhances antibody production (IgA) Promotes proliferation and IgG secretion by B-cell lines and induces hapten-specific IgG secretion in vitro by in vivo–primed B cells Promotes differentiation by normal B cells Stimulates eosinophil production and differentiation (GM-CSF and IL-3 act synergistically with IL-5 to stimulate eosinophil proliferation and differentiation) Enhances synthesis of IL-2 receptors
Interleukin-6	B-cell–stimulating factor-2 (BSF-2) Interferon-β_2 T-cell activation factor Hybridoma growth factor	B-cell differentiation and IgG secretion T cells activated to cytotoxicity Synergizes with IL-3 on early marrow myeloid stem cells and stimulates proliferation and differentiation of granulocytes, macrophages, eosinophils, mast cells, and megakaryocytes, as well as platelet production (may be a thrombopoietin)
Interleukin-7	Lymphopoietin-1	Stimulates pre–B-cell production Stimulates T-cell proliferation
Interleukin-8*	Neutrophil-activating factor T-cell chemotactic factor	Inflammatory mediator; stimulates activation of neutrophils
Interleukin-9		Stimulates erythroid colony formation and proliferation of a megakaryocyte cell line

TABLE 32.14 Major Effects of Hemolymphopoietic Growth Factors and Cytokines—cont'd

Cytokine	Other Names	Biologic Effects
Interleukin-10	Cytokine synthesis–inhibiting factor	Inhibits cytokine production by T_H1 cells
Interleukin-11		Stimulates B-cell, megakaryocyte, and mast cell lineages
C-kit ligand	Mast cell factor Stem cell factor Hemolymphopoietic growth factor-1	Acts on relatively early stem cells synergistically with other cytokines Stimulates pre-B cells

*Not considered a true growth factor but included here for completeness.

AML, Acute myeloblastic leukemia; *IgA*, immunoglobulin A; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M; *MHC*, major histocompatibility complex; *T_H1*, first of the thymus-derived cells.

in a 70-kg adult to an adequate level and platelet-induced clotting dysfunction to normal. Only 30,000 to 50,000 normally functioning platelets per milliliter are needed for normal clotting. One platelet transfusion will increase the platelet count from 5,000 to 20,000/mL blood; the platelet half-life is approximately 8 hours.

Heparin-induced thrombocytopenia can develop within hours on reexposure to heparin in a previously sensitized patient; prevalence has been shown to be increasing, particularly in ICU populations.[398c] The diagnosis starts with a clinical assessment, most commonly the 4-T score (Thrombocytopenia, Timing of fall, presence of Thrombosis, and other causes for Thrombocytopenia), with enzymatic immunoassays for confirmation.[398d] Treatment can be initiated prior to confirmatory test results, if suspicion is high. Argatroban is a direct thrombin inhibitor effective as therapy for heparin-induced thrombocytopenia.[399]

Major risk factors for thrombosis include factor V Leiden and prothrombin 20210A mutations, elevated plasma homocysteine, and the antiphospholipid antibody syndrome.[400,401] Clinicians facing these challenging patients may seek expert local consultation for help with management. This issue is discussed more fully in Chapter 50.

Hemophilia and Related Clotting Disorders

Abnormalities in blood coagulation as a result of defects in plasma coagulation factors are either inherited or acquired. Inherited disorders include X-linked hemophilia A (a defect in factor VIII activity), von Willebrand disease (defect in the von Willebrand component of factor VIII), hemophilia B (a sex-linked deficiency of factor IX activity), and other less common disorders. The sex-linked origin of some of these disorders means that hemophilia occurs almost exclusively in the male children of female carriers; men do not transmit the disease to their male children.

In elective surgery, levels of the deficient coagulation factor should be assayed 48 hours preoperatively and the level restored to 40% of normal before the surgical procedure. One unit of factor concentrate per kilogram of body weight normally increases the factor concentration by 2%. Thus, in an individual essentially devoid of activity, administration of 20 units/kg body weight would be required as an initial dose. Because the half-life is 6 to 10 hours for factor VIII and 8 to 16 hours for factor IX, approximately 1.5 units/h/kg of factor VIII or 1.5 units/2 hours/kg of factor IX should be given. Additional administration of factors VIII and IX should be guided by the activity of the clotting factors for approximately 6 to 10 days postoperatively.[402-404]

An antibody that inactivates factor VIII or IX (fresh frozen plasma fails to increase clotting factor activity after incubation with the patient's plasma) develops in approximately 10% of patients with either hemophilia A or B. These acquired anticoagulants are usually composed of IgG, are poorly removed by plasmapheresis, and are variably responsive to immunosuppressive drugs. The use of prothrombin complex concentrates can be lifesaving to bypass the inhibitor.

Patients who come to the operating room after having received many units of blood (as in massive GI bleeding and trauma) may have deficient clotting caused by depletion of platelets and later coagulation factors, which occurs after administration of approximately 10 units of blood. Treatment of these deficiencies can be corrected with platelet concentrates and fresh frozen plasma. In settings of massive hemorrhage requiring large volume transfusion, the approximation of whole blood through a one to one to one ratio of packed red blood cells to plasma to platelets can be advantageous.

Urokinase, streptokinase, and tissue-type plasminogen activator (t-PA) have been used to treat pulmonary embolism, deep vein thrombosis, stroke, and arterial occlusive disease. These drugs accelerate the lysis of thrombi and emboli, in contrast to heparin, which may prevent and slow propagation, but will not dissolve a thrombus. Bleeding complications associated with these fibrinolytic agents are the result of dissolution of hemostatic plugs and can be quickly reversed by discontinuing the medication and replenishing plasma fibrinogen with cryoprecipitate or plasma. However, cryoprecipitate and plasma are seldom needed preoperatively because the fibrinolytic activity of urokinase and streptokinase usually dissipates within 1 hour of discontinuing their administration. Nonetheless, insufficient data have accumulated to prescribe the ideal preoperative preparation and intraoperative management of hemostasis in patients recently treated with urokinase, streptokinase, or t-PA. Postponing surgery for three half-lives of the drug (increases in plasmin activity in blood can be assayed for ≥4 to 8 hours) may not be possible, and meticulous observation of the operative field for hemostasis may not suffice.[405,406] The process may be even more complex in a patient with a vascular or cardiac condition who requires heparin administration intraoperatively. To correct the fibrinogen deficiency in these patients, some clinicians administer fibrinogen as cryoprecipitate preoperatively, and EACA at heparin administration.

DDAVP has been used in operations associated with high blood loss as a routine measure to decrease bleeding and transfusion requirements. DDAVP therapy began as treatment of platelet dysfunction in von Willebrand disease but has since expanded to routine use in patients undergoing cardiovascular surgery and to frequent use in other high-blood loss operations. A meta-analysis of cardiac surgery concluded that DDAVP was not associated with a clinically significant reduction in exposure to blood transfusion in unselected patients, and therefore the authors were unable to recommend the routine use of DDAVP in patients exposed to CPB.[407] However, DDAVP may reduce postoperative bleeding in patients who have received preoperative aspirin within 7 days of surgery, patients with CPB times in excess of 140 minutes, and patients with demonstrable platelet dysfunction. The authors suggested that DDAVP could be used selectively in these subgroups.

ONCOLOGIC DISEASE

Patients with malignant tumors may be otherwise healthy or may be chronically ill with nutritional, neurologic, metabolic, endocrinologic, electrolyte, cardiac, pulmonary, renal, hepatic, hematologic, or pharmacologic disabilities. Thus determining the other morbidities accompanying malignant tumors requires through evaluation of all systems. Abnormalities frequently accompanying such tumors include hypercalcemia either by direct bone invasion or by ectopic elaboration of PTH or other bone-dissolving substance, uric acid nephropathy, hyponatremia (especially with small cell, or oat cell, carcinoma of the lung), nausea, vomiting, anorexia and cachexia, fever, tumor-induced hypoglycemia, intracranial metastases (10%-20% of all cancers), peripheral nerve or spinal cord disorders, meningeal carcinomatosis, toxic neuropathies secondary to anticancer therapy, and paraneoplastic neurologic syndromes (dermatomyositis, Eaton-Lambert syndrome, myopathies, and distal neuropathies).

Many patients with malignant tumors are given large doses of analgesics and should be kept comfortable during the perioperative period, it is of particular importance in terminally ill patients.[408] Immunomodulators, stimulating factors or cytokines, gene identification,[409,410] and drugs for treating side effects (e.g., midazolam, ondansetron, and even marijuana) have given new hope for safer, more effective therapy with fewer limiting side effects. The effect of ondansetron in preventing vomiting and the effect of midazolam in preventing memory-stimulated vomiting have been important additions. The neurokinin-1 antagonists have also been approved for treatment in oncologic patients.

The toxicity of cancer chemotherapy is related to the drugs used and the dose. For radiation therapy, damage occurs when the following doses are exceeded: lungs, 1500 rad; kidneys, 2400 rad; heart, 3000 rad; spinal cord, 4000 rad; intestine, 5500 rad; brain, 6000 rad; and bone, 7500 rad. The toxicities of biologic and immunomodulating therapies are related to the change in immune function that they cause. Alkylating agents cause bone marrow depression, including thrombocytopenia, as well as alopecia, hemorrhagic cystitis, nausea, and vomiting. The alkylating agents, including cyclophosphamide and mechlorethamine, can act as an anticholinesterase and prolong neuromuscular blockade.[411] The antineoplastic alkaloid vincristine produces peripheral neuropathy and SIADH, and vinblastine produces myelotoxicity. Cisplatin is also associated with peripheral neuropathy and severe nausea. Nitrosoureas can produce severe hepatic and renal damage, as well as bone marrow toxicity, myalgia, and paresthesia. Folic acid analogues such as methotrexate have been linked to bone marrow depression, ulcerative stomatitis, pulmonary interstitial infiltrates, GI toxicity, and occasionally, severe liver dysfunction. Fluorouracil and floxuridine, both pyrimidine analogues, cause bone marrow toxicity, megaloblastic anemia, nervous system dysfunction, and hepatic and GI alterations. Purine analogues (mercaptopurine, thioguanine) have bone marrow depression as their primary toxic effect. Anthracycline antibiotics (doxorubicin, daunorubicin, mithramycin, mitomycin C, bleomycin) can all cause pulmonary infiltrates, cardiomyopathy (especially doxorubicin and daunorubicin), myelotoxicity, and GI, hepatic, and renal disturbances. Knowing these expected side effects and complications allow general anesthesia to be safely provided to this patient population with the appropriate preoperative plan.

Patients Given Drug Therapy for Chronic and Acute Medical Conditions

A steadily increasing number of potent drugs are being used to treat disease, and the average hospitalized patient receives more than 10 drugs. Many drugs have side effects that may make anesthesia challenging and patient management more difficult. Knowing the pharmacologic properties and potential side effects of commonly used drugs helps the anesthesiologist avoid pitfalls during anesthesia and surgery.

ANTIHYPERTENSIVE DRUGS

ACE inhibitors (e.g., captopril, enalapril, and lisinopril) and angiotensin II receptor blockers (e.g., valsartan, candesartan) are being used increasingly as first-line drugs and appear to improve the quality of life of patients taking antihypertensive drugs. ACE inhibitors and angiotensin II receptor blockers may be associated with more peripheral vasodilation and hypotension on induction of anesthesia than are sympatholytic agents. Both ACE inhibitors and angiotensin II receptor blocking agents are associated with such severe hypotension with standard anesthetic induction that we discontinue or at least consider discontinuing the use of these drugs preoperatively (see earlier).

Catecholamine or sympathetic receptor blocking drugs affect the three major types of catecholamine receptors: α-adrenergic, β-adrenergic, and dopaminergic. The existence of subdivisions (e.g., β_1 and β_2) suggested the possibility that some drugs would be found to affect only one set of receptors. For example, terbutaline is used more frequently than isoproterenol because terbutaline is said to exert a preferential effect on β-$_2$ receptors (i.e., dilation of bronchial smooth muscle), thereby avoiding the cardiac stimulation produced by drugs that stimulate β_1-receptors. In fact, the selectivity is dose related. At a certain dose, a direct β_2-receptor stimulating drug affects only those receptors but, at a higher dose, stimulates both β_1 and β_2 receptors. The effect of a given dose varies with each patient. A certain dose may stimulate β_1 and β_2 receptors in one patient but neither receptor in another patient. More and more selective blocking drugs are being developed in the hope of widening the margin among β_1-, β_2-, and α-adrenergic effects. Ultimately, however, even more selectivity is desired. It would be advantageous to be able to decrease the heart rate without changing myocardial contractility or to increase contractility without changing the heart rate.

Metoprolol, atenolol, propranolol, betaxolol, timolol, esmolol, pindolol, oxprenolol, acebutolol, carteolol, penbutolol, and nadolol are widely available β-adrenergic receptor blocking drugs used for therapy in the United States. Because nadolol has poor lipid solubility, it has a long elimination half-life

(17-24 hours) and does not cross the blood-brain barrier readily. Although selective β-adrenergic receptor blocking drugs should be more appropriate in patients with increased airway resistance or diabetes, this advantage is apparent only when low doses are used. The use of β-adrenergic receptor blocking drugs has become widespread because these drugs treat everything from angina and hypertension to priapism and stage fright. These drugs appear to decrease morbidity and mortality in patients who have initially survived MI, and they may increase perioperative survival in selected patients.[412,413]

When administration of β-adrenergic receptor blocking drugs is terminated, sympathetic stimulation often increases, as though the body had responded to the presence of these drugs by increasing sympathetic neuron activity. Thus propranolol and nadolol withdrawal can be accompanied by a hyper–β-adrenergic condition that increases myocardial oxygen demands. Administering propranolol or metoprolol can cause bradycardia, exacerbations of decompensated heart failure, fatigue, dizziness, depression, psychoses, bronchospasm, and Peyronie disease. The POISE study emphasized the concerns that inadequate titration of these agents can lead to stroke or increased mortality.[111] Side effects of dopaminergic receptor blocking drugs are discussed later.

Prazosin, terazosin, and oxazocine are α_1-adrenergic receptor blocking drugs used to treat hypertension, ischemic cardiomyopathy, receding hairlines, and benign prostatic hypertrophy because they dilate both veins and arteries and reduce sphincter tone. These drugs are associated with vertigo, palpitations, depression, dizziness, weakness, and anticholinergic effects.

Some sympathomimetic drugs stimulate α-adrenergic receptors in the brainstem. Clonidine, a drug with a half-life of 12 to 24 hours, dexmedetomidine, and guanfacine are α_2-adrenergic receptor stimulants. Presumably, α_2-adrenergic agonists, including clonidine, dexmedetomidine, and guanfacine, lower arterial blood pressure on a long-term basis through the central brainstem adrenergic stimulation referred to previously. They may also be used on a long-term basis to treat opiate, cocaine, food, and tobacco withdrawal. Occasionally, withdrawal from clonidine can precipitate a sudden rebound hypertensive crisis. Tricyclic antidepressant drugs and presumably phenothiazines and the butyrophenones interfere with the action of clonidine. Although administration of a butyrophenone (e.g., droperidol) to a patient taking clonidine, dexmedetomidine, or guanfacine on a long-term basis could theoretically precipitate a hypertensive crisis, this has not been reported. Clonidine administration can be accompanied by drowsiness, dry mouth, orthostatic hypotension, bradycardia, and impotence. Acute clonidine or dexmedetomidine administration decreases anesthetic requirements by at least 40% to 60%; long-term administration decreases requirements by 10% to 20%.[414,415] Because of the relative safety of these drugs and their ability to decrease anesthetic requirements, block narcotic-induced muscle rigidity, and provide pain relief, their popularity preoperatively, intraoperatively, and in ICU sedation is increasing dramatically.[414-418]

Three other classes of antihypertensive drugs affect the sympathetic nervous system indirectly: diuretics, arteriolar dilators, and calcium channel blocking agents. Thiazide diuretic drugs are associated with hypochloremic alkalosis, hypokalemia, hyperglycemia, hyperuricemia, and hypercalcemia. The potassium-sparing diuretic drug spironolactone is associated with hyperkalemia, hyponatremia, gynecomastia, and impotence. All diuretic drugs can cause dehydration. The thiazide diuretics and furosemide appear to prolong neuromuscular blockade.

The arteriolar dilator hydralazine can cause a lupus-like condition (usually with renal involvement), nasal congestion, headache, dizziness, CHF, angina, and GI disturbances. Such a syndrome is nonexistent with the other direct vasodilator on the U.S. market, minoxidil.

The calcium channel blocking drugs (slow-channel calcium ion antagonists) inhibit the transmembrane influx of calcium ions into cardiac and vascular smooth muscle. Such inhibition reduces the heart rate (negative chronotropy), depresses contractility (negative inotropy), decreases conduction velocity (negative dromotropy), and dilates coronary, cerebral, and systemic arterioles (Fig. 32.7).[419] Verapamil, diltiazem, and nifedipine all produce such effects, but to varying degrees and apparently by similar, but different mechanisms. These mechanisms relate to the three different classes of calcium channel antagonists that they represent: the phenylalkyl amines, the benzothiazepines, and the dihydropyridines, respectively. Nifedipine is the most potent of the three as a smooth muscle dilator, whereas verapamil and diltiazem have negative dromotropic and inotropic effects, and weak vasodilating properties. Diltiazem has weak vasodilating properties when compared with nifedipine and has less of an AV conduction effect than does verapamil. Thus verapamil and diltiazem can increase the PR interval and produce AV block. In fact, reflex activation of the sympathetic nervous system may be necessary during the administration of diltiazem, and especially during verapamil therapy, to maintain normal conduction. Clearly, verapamil and diltiazem must be titrated very carefully when a patient is already taking a β-adrenergic receptor blocking drug or when adding β-blocking drugs to a patient already taking verapamil or diltiazem.

The use of calcium channel blocking drugs has several important implications for anesthetic management.[419-421] First, the effects of inhaled and narcotic anesthetics and nifedipine in decreasing systemic vascular resistance, arterial blood pressure, and contractility may be additive. Similarly, verapamil and anesthetics (inhaled anesthetics, nitrous oxide, and narcotics) increase AV conduction times and additively decrease arterial blood pressure, systemic vascular resistance, and contractility. Second, verapamil and presumably the other calcium channel blocking drugs have been found to decrease anesthetic requirements by up to 25%. These drugs can produce neuromuscular blockade, and potentiate both depolarizing and nondepolarizing neuromuscular blocking drugs. Finally, because slow-channel activation of calcium is necessary to cause spasms of cerebral and coronary vessels, bronchoconstriction, and normal platelet aggregation, these drugs may have a role in treating cerebral vasospasm (nimodipine), coronary artery graft vasospasm (nicardipine), bronchoconstriction, and unwanted clotting disorders perioperatively. These drugs are highly protein bound and may displace or be displaced by other drugs that are also highly protein bound (e.g., lidocaine, bupivacaine, diazepam, disopyramide, and propranolol). Adverse consequences can be minimized by titrating the inhaled or narcotic drug to the hemodynamic and anesthetic effects. Hemodynamic, but not electrophysiologic, changes can usually be reversed by administering calcium. Reversal of the electrophysiologic effects may occur if high doses of β-adrenergic agonists are given.

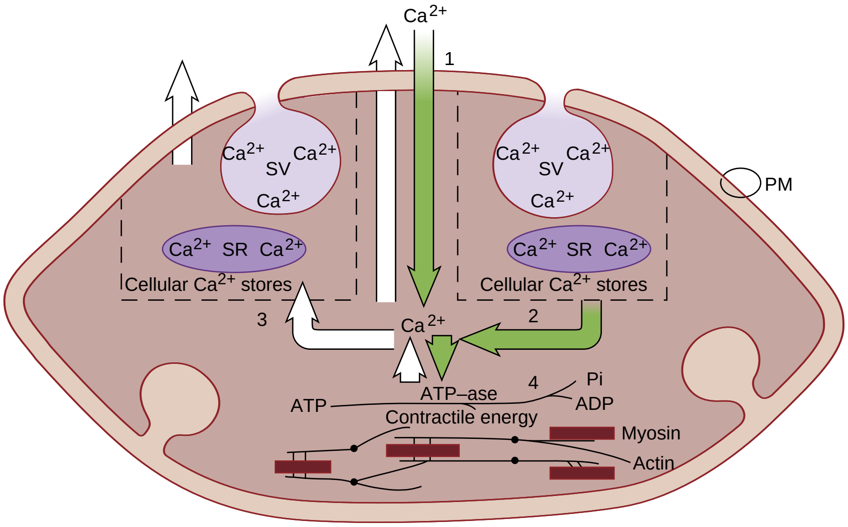


Fig. 32.7 Schematic drawing of a smooth muscle cell showing calcium *(Ca^{2+})* flux and possible sites of interference by halothane and nifedipine. The concentration of calcium in the cytoplasm increases *(green arrows)* because of entry through the plasma membrane *(PM)* and release from surface vesicles *(SV)* or the sarcoplasmic reticulum *(SR)*. When the concentration of cytoplasmic Ca^{2+} is sufficiently high, adenosine triphosphate *(ATP)* is activated. Splitting of ATP by adenosine triphosphatase *(ATPase)* into phosphatidylinositol *(Pi)* and adenosine diphosphate *(ADP)* provides the interaction and contraction of actin filaments and myosin particles constituting muscle fibers. The concentration of cytoplasmic Ca^{2+} decreases *(white arrows)* with the return of Ca^{2+} to cellular stores and the extracellular transport of Ca^{2+}. Both halothane and nifedipine probably (1) inhibit the entry of Ca^{2+} and (2) may also interfere with cytoplasmic Ca^{2+} flux by reducing the release of Ca^{2+} by the SR, by (3) reducing storage and reuptake, or by (4) blocking ATPase or the contractile mechanism (or both). (Redrawn from Tosone SR, Reves JG, Kissin I, et al. Hemodynamic responses to nifedipine in dogs anesthetized with halothane. *Anesth Analg.* 1983;62:903–908.)

MOOD-ALTERING DRUGS

Mood-altering drugs are the most frequently prescribed medications in the United States.[422,423] They include MAOIs, SSRIs, phenothiazines, tricyclic antidepressant drugs, other antidepressants that do not fall into previous drug category classifications such as bupropion, and drugs of abuse such as cocaine. MAOIs, which include isocarboxazid, phenelzine, pargyline, tranylcypromine, and deprenyl, bind irreversibly to the enzyme MAO, thereby increasing intraneuronal levels of amine neurotransmitters (serotonin, norepinephrine, dopamine, epinephrine). This increase is associated with an antidepressant effect, an antihypertensive effect, an antinarcoleptic effect, elevation of liver enzymes, and delayed onset of Parkinson disease. Because two forms of the enzyme (MAO-A and MAO-B) are selective in vitro for substrate (MAO-A is selective for serotonin, dopamine, and norepinephrine; MAO-B for tyramine and phenylethylamine), presumably MAOIs selective for MAO-A or MAO-B would have different effects.[424]

Interactions between MAOIs and a variety of foods and drugs containing indirect-acting sympathomimetic substances such as ephedrine or tyramine (found in aged hard cheeses) can occur for as long as 2 weeks after the last dose of MAOI is given. The most serious effects of this interaction are convulsions and hyperpyrexic coma (particularly after narcotics).

Anesthetic management of a patient given an MAOI can be challenging; for this reason it is widely accepted practice to discontinue MAOIs at least 2 to 3 weeks before any planned operation, further MAOIs are seen quite infrequently.[422-428] Severe reactions have occurred when too short an interval existed between the administration of MAOIs and tricyclic antidepressants. Emergency surgery in patients given MAOIs can be punctuated by hemodynamic instability. A regional block can be attempted as treatment of postoperative pain to avoid having to give narcotics. Cases of hyperpyrexic coma after the administration of most narcotics have been reported in humans, and animal studies document a 10% to 50% incidence of hyperpyrexic coma in animals pretreated with MAOIs and then given a variety of narcotics.[422-428] These reactions appear to be treated best by supportive care.

Alternative drugs for the treatment of severe depression include the tricyclic antidepressant drugs: amitriptyline, imipramine, desipramine, doxepin, nortriptyline, trazodone, and others.[422,423] Tricyclic antidepressant drugs also block the reuptake of neurotransmitters and cause their acute release. Given on a long-term basis, these drugs decrease stores of noradrenergic catecholamines. Tricyclic antidepressant drugs also produce side effects similar to those of atropine (dry mouth, tachycardia, delirium, urinary retention) and can cause changes on the ECG (changes in the T wave, prolongation of the QRS complex, bundle branch block or other conduction abnormalities, or PVCs). Although arrhythmias induced by tricyclic antidepressants have been treated successfully with physostigmine, bradycardia has sometimes occurred.[422,423] Drug interactions with tricyclic antidepressants include those related to blockade of the reuptake of norepinephrine. Such interactions, although predictable for a population of patients, may not alter a patient's threshold for arrhythmias. The selective serotonin reuptake inhibitors have gained popularity and include citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline, though these can also have serious side effects. For instance, fluoxetine causes nausea, vomiting, headaches, nervousness, and possibly paranoia and ideas of suicide more commonly than do the tricyclics[422,423]; however, it is less likely to cause systemic anticholinergic effects or orthostatic hypotension. Bupropion, which is fundamentally different than the SSRIs, may cause nausea, vomiting, seizures, agitation, tremor, excitement, and increased motor activity, but it only rarely causes anticholinergic effects or orthostatic hypotension. Discontinuing drugs can cause withdrawal symptoms or precipitate recurrence of psychiatric illness. Switching among drugs for depression can cause hyperpyrexia and coma; thus switching drugs preoperatively should not be requested casually.[422,423]

The effectiveness of phenothiazines and butyrophenones in schizophrenia suggests a dopamine receptor blocking action. In addition, these drugs possess varying degrees of parasympathetic stimulation and ability to block α-adrenergic receptors. The phenothiazines include chlorpromazine, promazine, triflupromazine, fluphenazine, trifluoperazine, prochlorperazine, and many others. The butyrophenones include droperidol and haloperidol. Both the phenothiazines and butyrophenones produce sedation, depression, and antihistaminic, antiemetic, and hypothermic responses. They are also associated with cholestatic jaundice, impotence, dystonia, and photosensitivity. Other side effects associated with phenothiazines include orthostatic hypotension (partly as a result of α-adrenergic blockade) and abnormalities on the ECG such as prolongation of the QT or PR intervals, blunting of T waves, depression of the ST segment, and on rare occasion, PVCs and torsades de pointes.[422,423,429,430]

Several important drug interactions are noteworthy for the phenothiazine derivatives. The effects of CNS depressants (especially narcotics and barbiturates) are enhanced by the concomitant administration of phenothiazines. In addition, the CNS seizure threshold is lowered by the administration of phenothiazines, which should be avoided in patients who are epileptic or withdrawing from any drug that depresses the CNS. Lithium carbonate is used to treat manic depression, but it is more effective in preventing mania than in relieving depression. In excitable cells, lithium mimics sodium and decreases the release of neurotransmitters both centrally and peripherally. Lithium prolongs neuromuscular blockade and may decrease anesthetic requirements because it blocks brainstem release of norepinephrine, epinephrine, and dopamine.

Psychoactive drugs such as the amphetamines (including methamphetamines, and crystal methamphetamine) and cocaine acutely release norepinephrine, epinephrine, and dopamine and block their reuptake. Taken on a long-term basis, they deplete nerve endings of these neurotransmitters.

Drugs that appear to increase central α-adrenergic release increase anesthetic requirements, whereas drugs that appear to decrease central α-adrenergic release decrease anesthetic requirements. (This may not be the mechanism by which they alter anesthetic requirements, but it is a convenient way of remembering the alteration.) Drugs that affect only the β-adrenergic receptors do not alter anesthetic requirements.

ANTIARRHYTHMIC DRUGS

Antiarrhythmic drugs include local anesthetics (lidocaine, procaine), anticonvulsant (phenytoin), β-adrenergic blocking agents, calcium channel blocking drugs, or primary antiarrhythmic drugs. These drugs are classified into five major categories: local anesthetics that alter phase 0 and phase 4 depolarization (quinidine, procainamide, and flecainide), local anesthetics that affect only phase 4 depolarization (lidocaine, mexiletine, tocainide, phenytoin, encainide), β-adrenergic receptor antagonists, antiadrenergic drugs (bretylium, disopyramide, amiodarone), and calcium entry blockers. A lack of adverse reports does not imply that all these drugs should be continued through the time of surgery.

The pharmacologic characteristics of the various antiarrhythmic drugs can affect anesthetic management. Disopyramide is similar to quinidine and procainamide in its antiarrhythmic effectiveness. Disopyramide is excreted mainly by the kidneys, but hepatic disease increases its half-life. This drug often produces anticholinergic effects, including tachycardia, urinary retention, and psychosis. Hepatitis has also been reported to have occurred after its use.[431] Little is known of the interaction of bretylium with anesthetic agents; however, since it blocks the release of catecholamines, long-term therapy with this drug has been associated with hypersensitivity to vasopressors.[431] Quinidine depends on the kidneys for excretion, can produce vagolytic effects that can decrease AV block, and is associated with blood dyscrasias and GI disturbances.[431] Most of the antiarrhythmic drugs enhance nondepolarizing neuromuscular blockade. Reports have confirmed this enhancement for quinidine, phenytoin, lidocaine, procainamide, and propranolol.[432-440] No data document such an effect for depolarizing muscle relaxants. Amiodarone, an antiadrenergic drug used to treat recurrent supraventricular and ventricular tachycardia, causes thyroid dysfunction as a result of the large amount of iodine in its structure, as well as peripheral neuropathy, and has been associated with hypertension, bradyarrhythmias, and reduced cardiac output during anesthesia.[441] The drug has a half-life of 29 days, and its pharmacologic effects persist for more than 45 days after discontinuance.[442]

ANTIBIOTICS

Many antibacterial drugs are nephrotoxic or neurotoxic, or both, and many prolong neuromuscular blockade.[434-443] The only antibiotics devoid of neuromuscular effects appear to be penicillin G and the cephalosporins.[439] Most enzyme-inducing drugs do not increase the metabolism of the volatile agents. Appropriate antibiotic prophylaxis for surgery requires a knowledge of the probability of infection for that type of surgical procedure and, if the incidence of infection warrants, the use of a drug regimen directed against the most likely infecting organisms.[443]

MEDICATIONS FOR GLAUCOMA

Medications for glaucoma include two organophosphates: echothiophate and isoflurophate. These drugs inhibit serum cholinesterase, which is responsible for the hydrolysis and inactivation of succinylcholine and ester-type local anesthetics such as procaine, chloroprocaine, and tetracaine.[444,445] These ester-type local anesthetics should be avoided in patients treated with eye drops containing organophosphate. Table 32.15 lists other medications related to anesthesia and their side effects (from the National Registry for Drug-Induced Ocular Side Effects, Oregon Health Sciences University, 3181 SW Sam Jackson Park Road, Portland, OR 97201; 503-279-8456).

TABLE 32.15 Common Ophthalmologic Drugs and Their Anesthetically Important Interactions

Drug (Trade Name)	Toxicities and Specific Treatments
GLAUCOMA: PRIMARY GOAL IS TO REDUCE IOP BY Miotics and epinephrine: increase outflow of aqueous humor β-Blockade and carbonic anhydrase inhibitors: reduce production of aqueous humor Osmotic drugs: transiently decrease volume	
MIOTICS Parasympathomimetics Pilocarpine (Adsorbocarpine, Isopto Carpine, Pilocar, Pilocel) Carbachol	
ACETYLCHOLINESTERASE INHIBITORS Physostigmine Demecarium Isoflurophate (Floropryl) Echothiophate (Echodide, Phospholine)	Tox: Hypersalivation, sweating, N/V, bradycardia, hypotension, bronchospasm, CNS effects, coma, respiratory arrest, death Rx: Atropine, pralidoxime (Protopam) Ix: Succinylcholine—prolonged apnea (drugs must be discontinued 4 weeks before)
EPINEPHRINE (EPITRATE, MUROCOLL, MYTRATE, EPIFRIN, GLAUCON, EPINAL, EPPY)	Tox: (rare) Tachycardia, PVCs, HTN, headache, tremors Ix: Avoid drugs that sensitize to catecholamines (e.g., halothane)
β-BLOCKERS Timolol (Timoptic) Betaxolol (Betoptic) Levobunolol (Betagan)	Tox: β-Blockade with bradycardia, exacerbation of asthma, CNS depression, lethargy, confusion Synergy noted with systemic drugs
CARBONIC ANHYDRASE INHIBITORS Acetazolamide (Diamox) Dichlorphenamide (Daranide, Oratrol) Ethoxzolamide (Cardrase, Ethamide) Methazolamide (Neptazane)	Tox: Anorexia, GI disturbances, "general miserable feeling" and malaise, paresthesias, diuresis, hypokalemia (transient), renal colic and calculi, hyperuricemia, thrombocytopenia, aplastic anemia, acute respiratory failure in patients with COPD
OSMOTIC DRUGS Glycerin (Glyrol, Osmoglyn) Isosorbide (Ismotic) Urea (Urevert, Ureaphil) Mannitol (Osmitrol) Intraocular acetylcholine (Miochol)	Tox: Dehydration, hyperglycemia, nonketotic hyperosmolar coma (rare); fatalities with mannitol secondary to CHF or intracranial bleeding; urea may cause thrombosis Tox: Hypotension, bradycardia Rx: Atropine
MYDRIATICS AND CYCLOPLEGICS: PROVIDE PUPILLARY DILATATION AND PARALYSIS OF ACCOMMODATION Anticholinergics block muscarinic receptors; paralyzing in iris α-Adrenergics contract the dilator of the iris	
ANTICHOLINERGICS Atropine (Atropisol, Bufopto, Isopto Atropine) Cyclopentolate, alone (Cyclogyl) or with phenylephrine-homatropine (Cyclomydril) Homatropine (Homatrocel, Isopto Homatropine) Scopolamine (Isopto Hyoscine, Murocoll 19) Tropicamide (Mydriacyl)	Tox: Dry mouth, flushing, thirst, tachycardia, seizure, hyperactivity, transient psychosis, rare coma, and death Rx: Physostigmine
β-ADRENERGICS Phenylephrine (Efricel, Mydfrin, Neo-Synephrine) Hydroxyamphetamine (Paredrine)	Tox: Tachycardia, HTN, PVCs, myocardial ischemia, agitation

CHF, Congestive heart failure; *CNS,* central nervous system; *COPD,* chronic obstructive pulmonary disease; *GI,* gastrointestinal; *HTN,* hypertension; *IOP,* intraocular pressure; *Ix,* interaction; *N/V,* nausea and vomiting; *PVCs,* premature ventricular contractions; *Rx,* treatment; *Tox,* toxicity.

Anesthetic Implications of Complementary and Alternative Therapies

SHIQIAN SHEN and LUCY LIN CHEN

KEY POINTS

- Herbal medication use has increased dramatically in the overall population and particularly in preoperative patients.
- Patients might not volunteer information unless they are queried specifically about herbal medication use.
- Although many commonly used herbs have side effects that affect drug metabolism, bleeding, and neuronal function, they are not subject to regulations on purity, safety, and efficacy.
- Knowledge of specific interactions and metabolism of herbs can provide practical guidelines to facilitate perioperative management.
- Other complementary therapies, including acupuncture and music therapy, have become increasingly popular and have shown positive results for certain pain conditions, albeit high-quality data are still lacking.
- Dietary supplements may influence gut microbiota, a consortium of diverse microorganisms residing in the gastrointestinal tract, which represents a new research frontier in perioperative medicine.

Complementary and alternative medicine (CAM) has implications for physicians in general, but has particular importance for the perioperative period because of specific complications associated with certain therapies. Complementary medicine is defined as the addition of nonconventional therapies to accepted treatments; alternative medicine describes the use of nonconventional therapies in lieu of accepted treatments. They have become an important part of contemporary health care. The more popular term of "integrative health or integrative medicine" is used when complementary approaches are incorporated into mainstream health care.

According to a 2012 U.S. National Health Interview Survey (NHIS), 33.2% of adults and 11.6% of children (4-17 years of age) have used CAM.[1,1a] Visits to CAM practitioners exceed those to American primary care physicians,[2] and CAM is even more widely used in Europe, where herbal medicines are prescribed more frequently than conventional drugs are. Furthermore, patients undergoing surgery appear to use CAM more than the general population does.[3] Aside from the widespread use of CAM, perioperative physicians have a special interest in CAM therapies for several reasons. First, several commonly used herbal medications exhibit direct effects on the cardiovascular and coagulation systems. Second, some CAMs can interfere with conventional medications that are commonly given in the postoperative period. Finally, the therapeutic potential of CAM in the perioperative period is increasingly being described in the literature for reducing postoperative nausea, vomiting, and pain.

Despite the public enthusiasm for CAM, scientific knowledge in this area is still incomplete and often confusing for practitioners and patients. One recent study confirmed poor knowledge of this subject among physicians.[4] Recommendations for clinicians are often based on small clinical trials, case reports, animal studies, predictions derived from known pharmacology, and expert opinion. Research is essential because CAM therapies are often widely adopted by the public before adequate data are available to support their safety and efficacy. In 1991, Congress established the Office of Alternative Medicine, which is now known as the National Center for Complementary and Integrative Health. It operates within the National Institutes of Health.

Based on the 2012 NHIS study, the most commonly used CAMs were natural products, deep breathing exercises, meditation, chiropractic or osteopathic manipulation, massage, and yoga. Interestingly, a 2017 NHIS survey noted increases in the use of yoga and meditation by both adults and children (https://nccih.nih.gov/research/statistics/NHIS, Accessed 11/13/2018/tg). CAM practices can be classified into three general categories (Box 33.1).[5] This chapter is not intended as a comprehensive review of CAM. Specific therapies relevant to anesthesia are discussed, with a focus primarily on herbal medicines. Nonherbal dietary supplements, acupuncture, and music are also considered because they are relevant to perioperative care.

BOX 33.1 **Three Major Categories of Complementary and Alternative Medicine**

1. Natural products: this group includes a variety of products, such as herbs (also known as botanicals),vitamins and minerals, and probiotics. They are widely marketed, readily available to consumers, and often sold as dietary supplements.
2. Mind-body practices: yoga, chiropractic and osteopathic manipulation, meditation, and massage therapy are among the most popular mind and body practices used by adults. Other mind and body practices include acupuncture, relaxation techniques (such as breathing exercises, guided imagery, and progressive muscle relaxation), tai chi, qi gong, and hypnotherapy.
3. Others: traditional healers, Ayurvedic medicine, traditional Chinese medicine, homeopathy, naturopathy, and functional medicine.

Herbal Medicines

Preoperative use of herbal medicines has been associated with adverse perioperative events.[6] Surveys estimate that 22% to 32% of patients undergoing surgery use herbal medications.[7-9] In a recent retrospective review, 23% of surgery patients indicated the use of natural products, and older patients preferred dietary supplements.[10]

Herbal medicines can affect the perioperative period through several classic mechanisms: direct effects (i.e., intrinsic pharmacologic effects), pharmacodynamic interactions (i.e., alteration of the action of conventional drugs at effector sites), and pharmacokinetic interactions (e.g., alteration of the absorption, distribution, metabolism, and elimination of conventional drugs). Because approximately 50% of herbal medicine users take multiple herbs concomitantly[7] and 25% of herbal medicine users take prescription drugs,[11] adverse effects are difficult to predict and attribute.

Herbal medicines are associated with unique problems not usually found with conventional drugs.[12] Many of the issues complicating the understanding of herbal medications derive from the fact that they are classified as dietary supplements under the Dietary Supplement Health and Education Act of 1994. As such, the introduction of herbal medications does not require animal studies, clinical trials, or postmarketing surveillance. Under current law, the burden is shifted to the U.S. Food and Drug Administration (FDA) to prove products unsafe before they can be withdrawn from the market, such as the withdrawal of intranasal Zicam (cold medicine) after more than 130 reports of persistent anosmia.[13] Commercial herbal medicine preparations can have unpredictable pharmacologic effects resulting from inaccurate labeling, misidentified plants, adulterants, variations in natural potency, and unstandardized processing methods.

Two of the major problems confronting herbal medicine research involve quality control and added adulterants. In a recent clinical trial to treat human H1N1 influenza, an herbal formulation containing 12 different Chinese herbal medicines including licorice (genus *Glycyrrhiza*) was used.[14] Some of the other botanicals in the formula were not accurately identified. There are three *Glycyrrhiza* species on the market that may show a twofold difference when the three species are compared.[15]

Labeled active ingredients can vary tenfold in different commercial preparations.[16] In June 2007, the FDA issued regulations for current good manufacturing practices (GMPs) for dietary supplements.[17] This rule requires that proper controls be in place so that dietary supplements are processed in a consistent manner and meet quality standards. Especially emphasized are the identity, purity, strength, and composition of the products. Dietary products adhering to GMPs undoubtedly reduce the potential risk in the use of herbal medicines. Because this rule is somewhat similar to that for prescription drug GMPs, many supplement manufacturers believe that it is not practical for botanicals.[18]

Beyond quality control is the inclusion of biologically active pharmacologic adulterants in herbal medications and supplements. There are clinical consequences when quality control is lacking or herbal preparations are adulterated, as found in a weight-loss remedy study that revealed one manufacturer's incorrect substitution of an herb for another when the carcinogen aristolochic acid led to an outbreak of nephropathy and urothelial carcinoma.[19] In another event, more than 14 million capsules of asexual enhancement supplement were recalled because the compound on the label did not actually exist and the supplement did contain an analogue of sildenafil, which has not been tested in humans.[20] In light of these events, in August 2016, the FDA proposed a new guidance to evaluate the safety of supplements based on their history of use, formulation, proposed daily dose, and recommended duration of use. Although the guidance represents only a fraction of what is necessary for a new drug application, it requires some testing for tolerability in animals, but not in humans,[21] when products are marketed for consumption at doses substantively greater than those historically ingested. Any ingredient formulated or prepared in a novel manner is considered a new ingredient.

In this section, we discuss the preoperative assessment and management of patients who use herbal medicines and examine 11 herbal medicines that have the greatest effect on perioperative patient care: *Echinacea*, ephedra, garlic, ginger, *Ginkgo biloba*, ginseng, green tea, kava, saw palmetto, St. John's wort, and valerian (Table 33.1).

Preoperative Assessment and Management

Preoperative assessment should address the use of herbal medicines (see Table 33.1). One study found that 90% of anesthesia providers do not routinely ask about herbal medicine use.[22] Moreover, more than 70% of patients are not forthcoming about their herbal medicine use during routine preoperative assessment.[7] When a positive history of herbal medicine use is elicited, one in five patients is unable to properly identify the preparation being taken.[23] Asking patients to bring their herbal medicines

TABLE 33.1 Clinically Important Effects, Perioperative Concerns, and Recommendations for Perioperative Discontinuation of 11 Commonly Used Herbal Medicines

Herbs (Common Names)	Pharmacologic Effects	Perioperative Concerns	Discontinue Before Surgery
Echinacea (purple cone-flower root)	Activation of cell-mediated immunity	Allergic reactions Decreases effectiveness of immunosuppressants Potential for immunosuppression with long-term use	No data
Ephedra (ma huang)	Increases heart rate and blood pressure through direct and indirect sympathomimetic effects	Risk of myocardial ischemia and stroke from tachycardia and hypertension Ventricular arrhythmias with halothane Long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability Life-threatening interaction with MAO inhibitors	24 h
Garlic (ajo)	Inhibits platelet aggregation (may be irreversible) Increases fibrinolysis Equivocal antihypertensive activity	May increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	7 days
Ginger	Antiemetic Antiplatelet aggregation	May increase risk of bleeding	No data
Ginkgo (duck-foot tree, maidenhair tree, silver apricot)	Inhibits platelet-activating factor	May increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	36 h
Ginseng (American ginseng, Asian ginseng, Chinese ginseng, Korean ginseng)	Lowers blood glucose Inhibits platelet aggregation (may be irreversible) Increased PT/PTT in animals	Hypoglycemia May increase risk of bleeding May decrease anticoagulant effect of warfarin	7 days
Green tea	Inhibits platelet aggregation Inhibits thromboxane A2 formation	May increase risk of bleeding May decrease anticoagulant effect of warfarin	7 days
Kava (awa, intoxicating pepper, kawa)	Sedation Anxiolysis	May increase sedative effect of anesthetics Increase in anesthetic requirements with long-term use unstudied	24 h
Saw palmetto (dwarf palm, *Sabal*)	Inhibits 5α-reductase Inhibits cyclooxygenase	May increase risk of bleeding	No data
St. John's wort (amber, goat weed, hardhay, hypericum, Klamath weed)	Inhibits neurotransmitter reuptake MAO inhibition unlikely	Induction of cytochrome P450 enzymes; affects cyclosporine, warfarin, steroids, and protease inhibitors; may affect benzodiazepines, calcium channel blockers, and many other drugs Decreased serum digoxin levels Delayed emergence	5 days
Valerian (all heal, garden heliotrope, vandal root)	Sedation	May increase sedative effect of anesthetics Benzodiazepine-like acute withdrawal May increase anesthetic requirements with long-term use	No data

MAO, Monoamine oxidase; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

and other dietary supplements with them at the time of the preoperative evaluation would be helpful. A positive history of herbal medicine use should alert one to the presence of undiagnosed disorders causing symptoms leading to self-medication. Patients who use herbal medicines may be more likely to avoid conventional diagnosis and therapy.[24]

In general, herbal medicines should be discontinued preoperatively. Patients who require nonelective surgery are not evaluated until the day of surgery or are noncompliant with instructions to discontinue herbal medications preoperatively. In this situation, anesthesia can usually proceed safely at the discretion of the anesthesia provider, who should be familiar with commonly used herbal medicines. For example, recent use of herbal medicines that inhibit platelet function (e.g., garlic, ginseng, *G. biloba*) may warrant specific strategies for procedures with substantial intraoperative blood loss (e.g., platelet transfusion) and those that alter the risk-benefit ratio of using certain anesthetic techniques (e.g., neuraxial blockade).

Preoperative discontinuation of all herbal medicines might not eliminate complications related to their use. Withdrawal of some of the herbal medicines can increase morbidity and mortality after surgery similar to regular medications.[25,26] The danger of abstinence after long-term use may be similar with herbal medicines such as valerian, which can produce acute withdrawal after long-term use.

Although the American Society of Anesthesiologists has no official standard or guideline for the preoperative use of herbal medications, public and professional educational information released by this organization suggests that herbals be discontinued at least 2 weeks before surgery.[25] Our review of the literature favors a more targeted approach. When pharmacokinetic data for the active constituents in an herbal medication are available, the timeframe for preoperative discontinuation can be tailored. Some herbal medications are eliminated quickly and may be discontinued near the time of surgery. For other herbal medicines, 2 weeks is recommended.[27]

Evidence-based estimates of herbal safety in the perioperative period are limited. One study of 601 patients who used traditional Chinese herbal medications suggested an infrequent rate of potential serious complications.[28] Clinicians should be familiar with commonly used herbal medications to recognize and treat any complications that might arise. Table 33.1 summarizes the clinically important effects, perioperative concerns, and recommendations for preoperative discontinuation of the 11 herbal medications that account for 30% of the dietary supplements sold in the United States.[29] The type of surgery and potential perioperative course should be considered in these clinical recommendations.

ECHINACEA

Three species of *Echinacea*, a member of the daisy family, are used for the prophylaxis and treatment of viral (decreasing the incidence and duration of the common cold), bacterial, and fungal infections, particularly those of upper respiratory origin, although its efficacy in fungal infections is doubtful.[30,31] The biological activity of *Echinacea* could be immunostimulatory, immunosuppressive, or antiinflammatory.[32] Although studies have not specifically addressed interactions between *Echinacea* and immunosuppressive drugs, experts generally warn against the concomitant use of *Echinacea* and these drugs because of the probability of diminished effectiveness.[33,34] In contrast to its immunostimulatory effects with short-term use, long-term use of more than 8 weeks is accompanied by the potential for immunosuppression[34] and a theoretically increased risk for postsurgical poor wound healing and opportunistic infections. A recent phytochemical study identified a potential immunosuppressant compound from *Echinacea*—cynarine.[35]

Information about Echinacea's pharmacokinetics is still limited.[36] *Echinacea* significantly reduced plasma concentrations of S-warfarin, but did not significantly affect warfarin pharmacodynamics and platelet aggregation in healthy subjects.[37] However, this herb should be discontinued as far in advance of surgery as possible when compromises in hepatic function or blood flow are anticipated.[38] In the absence of definitive information, patients with preexisting liver dysfunction should be cautious in using *Echinacea*.

EPHEDRA

Ephedra, known as *ma huang* in Chinese medicine, is a shrub native to central Asia. It is used to promote weight loss, increase energy, and treat respiratory conditions such as asthma and bronchitis. Ephedra contains alkaloids, including ephedrine, pseudoephedrine, norephedrine, methylephedrine, and norpseudoephedrine.[25] Commercial preparations can be standardized to a fixed ephedrine content. Publicity about adverse reactions to this herb prompted the FDA to bar its sale in 2004, but ephedra is still widely available via the Internet.

Ephedra causes dose-dependent increases in arterial blood pressure and heart rate. Ephedrine, the predominant active compound, is a noncatecholamine sympathomimetic that exhibits α_1, β_1, and β_2 activity indirectly by releasing endogenous norepinephrine (noradrenaline). These sympathomimetic effects have been associated with more than 1070 reported adverse events, including fatal cardiac and central nervous system complications.[39] Vasoconstriction and, in some cases, vasospasm of coronary and cerebral arteries can cause myocardial infarction and thrombotic stroke.[40] Ephedra can also affect cardiovascular function by causing hypersensitivity myocarditis, characterized by cardiomyopathy with myocardial lymphocyte and eosinophil infiltration.[41] Long-term use results in tachyphylaxis from depletion of endogenous catecholamine stores and can contribute to perioperative hemodynamic instability. In these situations, direct-acting sympathomimetics may be preferred as first-line therapy for intraoperative hypotension and bradycardia. Concomitant use of ephedra and monoamine oxidase inhibitors can result in life-threatening hyperpyrexia, hypertension, and coma. Finally, continuous ephedra is a rare cause of radiolucent kidney stones.[42] Recently, there was a case report describing acute angle-closure glaucoma caused by ephedra.[42a]

The pharmacokinetics of ephedrine have been studied in humans.[43,44] Ephedrine has an elimination half-life of 5.2 hours, with 70% to 80% of the compound excreted unchanged in urine. Based on the pharmacokinetic data and the known cardiovascular risks associated with ephedra, including myocardial infarction, stroke, and cardiovascular collapse from catecholamine depletion, this herb should be discontinued at least 24 hours before surgery.

GARLIC

Garlic is one of the most extensively researched medicinal plants. It has the potential to modify the risk for atherosclerosis by reducing arterial blood pressure, thrombus formation, and serum lipid and cholesterol concentrations.[45] These effects are primarily attributed to its sulfur-containing compounds, particularly allicin and its transformation products. Commercial garlic preparations can be standardized to a fixed alliin and allicin content.

Garlic inhibits platelet aggregation in vivo in a concentration-dependent fashion. The effect of one of its constituents, ajoene, is irreversible and can enhance the effect of other platelet inhibitors such as prostacyclin, forskolin, indomethacin, and dipyridamole.[46] Although the effects are not consistently demonstrated in volunteers, there is one case described in an 80 year old who had a spontaneous epidural hematoma develop that was attributed to continuous garlic use.[47] Garlic has interacted with warfarin, resulting in an increased international normalized ratio (INR).[48]

In addition to bleeding concerns, garlic can decrease systemic and pulmonary vascular resistance in laboratory animals, but this effect is marginal in humans.[49] Although there are insufficient pharmacokinetic data on garlic's constituents, the potential for irreversible inhibition of platelet function may warrant discontinuation of garlic at least 7 days before surgery, especially if postoperative bleeding is a particular concern or other anticoagulants are given. Additionally, garlic's pharmacokinetics should be considered when a risk-benefit analysis is made for neuraxial techniques.

GINGER

Ginger (*Zingiber officinale*) is a popular spice with a long history of use in Chinese, Indian, Arabic, and Greco-Roman herbal medicines. Ginger has a wide range of reported health benefits for those with arthritis, rheumatism, sprains, muscular aches, pains, sore throats, cramps, constipation, indigestion, nausea, vomiting, hypertension, dementia, fever, infectious diseases, and helminthiasis.[50] Ginger contains up to 3% volatile oil, mostly monoterpenoids and sesquiterpenoids.[51] Gingerols are representative compounds in ginger.[52]

Ginger is an antiemetic and has been used to treat motion sickness and to prevent nausea after laparoscopy.[53] The number of postoperative antiemetic medications was significantly reduced after aromatherapy with essential oil of ginger.[54] In another recent trial, ginger supplementation reduced the severity of acute chemotherapy-induced nausea in adult cancer patients and compared favorably to conventional antiemetics.[55]

In an in vitro study, gingerols and related analogues inhibited arachidonic acid–induced human platelet serotonin release and aggregation, with a potency similar to that of aspirin.[52] In another in vitro study, the antiplatelet effects of 20 ginger constituents were evaluated. Five constituents showed antiplatelet activities at relatively low concentrations. One of the ginger compounds (8-paradol) was the most potent cyclooxygenase-1 inhibitor and antiplatelet aggregation drug.[56] In a case report, a ginger-phenprocoumon combination resulted in an increased INR and epistaxis.[57] Although the sample size was relatively small, the platelet inhibition potential of ginger has been suggested in a pilot clinical study.[58] This result may warrant the discontinuation of ginger at least 2 weeks before surgery,

GINKGO

Ginkgo is derived from the leaf of *G. biloba* and has been used for cognitive disorders, peripheral vascular disease, age-related macular degeneration, vertigo, tinnitus, erectile dysfunction, and altitude sickness. Studies have suggested that ginkgo can stabilize or improve cognitive performance in patients with Alzheimer disease and multiinfarct dementia,[59] but not in healthy geriatric patients.[60] The compounds that might be responsible for its pharmacologic effects are the terpenoids and flavonoids. The two ginkgo extracts used in clinical trials are standardized to ginkgo-flavone glycosides and terpenoids.

Ginkgo alters vasoregulation, acts as an antioxidant, modulates neurotransmitter and receptor activity, and inhibits platelet-activating factor. Of these effects, inhibition of platelet-activating factor is of primary concern for the perioperative period. Although bleeding complications have not occurred in clinical trials, four cases of spontaneous intracranial bleeding,[61-63] one case of spontaneous hyphema,[64] and one case of postoperative bleeding after laparoscopic cholecystectomy[65] have been described when ginkgo was being taken.

Terpene trilactones are highly bioavailable when administered orally. The elimination half-lives of the terpene trilactones after oral administration are between 3 and 10 hours. For ginkgolide B, a dosage of 40 mg twice daily resulted in a higher area under the curve, and a longer half-life and residence time, than after a single 80-mg dose. A once daily dose of 80 mg guaranteed a larger maximum concentration peak (T_{max}) that was reached 2 to 3 hours after administration.[66] The pharmacokinetics of terpene trilactones in three different ginkgo preparations in human plasma[67] indicate that ginkgo should be discontinued at least 2 weeks before surgery to avoid bleeding.[38]

GINSENG

Among the several species of ginseng used for their pharmacologic effects, Asian ginseng *(Panax ginseng)* and American ginseng *(Panax quinquefolius)* are the most commonly described.[68] Ginseng has been labeled an "adaptogen" because it reputedly protects the body against stress and restores homeostasis.[69] Because its pharmacologic actions are attributed to the ginsenosides, a group of compounds known as *steroidal saponins,* many commercially available ginseng preparations have been standardized to ginsenoside content.[68,70]

The many heterogeneous and sometimes opposing effects of different ginsenosides[71,72] give ginseng a broad but incompletely understood pharmacologic profile including general health, fatigue, immune function, cancer, cardiovascular disease, diabetes mellitus, cognitive function, viral infections, sexual function, and athletic performance.[69] The underlying mechanism is similar to that classically described for steroid hormones. This herb decreases postprandial blood glucose in both healthy and type 2 diabetes patients,[73] an effect that can create unintended hypoglycemia in patients who have fasted before surgery.

Ginseng can alter coagulation pathways. The antiplatelet activity of panaxynol, a constituent of ginseng, may be irreversible in humans.[74] Ginseng extract and ginsenosides inhibit platelet aggregation in vitro[75,76] and prolong thrombin time and activated partial thromboplastin time in in vivo animal models.[77,78]

The clinical evidence implicating ginseng as a cause of bleeding is weak and based on only a few case reports.[79] Although ginseng may inhibit the coagulation cascade, one case associated its use with a significant decrease in warfarin anticoagulation.[80] Subsequently, a study in volunteers showed that American ginseng interfered with warfarin-induced anticoagulation,[81] reducing its anticoagulant effect. When prescribing warfarin, clinicians should specifically ask about ginseng use. In another clinical trial, warfarin's clearance was moderately increased with Asian ginseng.[82] Because warfarin is often used after orthopedic or vascular procedures, this herbal drug interaction can affect perioperative management in many patients.

In rats, the elimination half-lives are different after an intravenous infusion of ginseng, with ginsenosides Re and Rg1 between 0.7 and 4 hours, and ginsenosides Rb1 and Rd between 19 and 22 hours.[83] After oral administration of ginseng, ginsenoside Rb1 reached the maximum plasma concentration at approximately 4 hours with a prolonged half-life.[84,85] These data suggest that ginseng should be discontinued at least 48 hours before surgery. Because platelet inhibition by ginseng may be irreversible, ginseng use should be stopped at least 2 weeks before surgery.[38]

GREEN TEA

Tea from the *Camellia sinensis* is one of the most ancient and the second most widely consumed beverage in the world.[86,87] Tea can be classified into different types, such as green, oolong, and black. Green tea, which is not fermented and is derived directly from drying and steaming fresh tea leaves, contains polyphenolic compounds. Catechins in green tea account for 16% to 30% of its dry weight. Epigallocatechin-3-gallate (EGCG), the most predominant catechin in green tea, is responsible for much of the biologic activity mediated by green tea.[86]

In an early in vitro and in vivo study, both green tea and EGCG significantly prolonged mouse tail bleeding time in conscious mice. They inhibited adenosine diphosphate- and collagen-induced rat platelet aggregation in a dose-dependent manner.[88] The antiplatelet activity can result from the inhibition of thromboxane A2 formation by preventing arachidonic acid liberation and thromboxane A2 synthase.[89,90] Regarding a possible adverse effect of green tea on platelets, one case reported thrombotic thrombocytopenic purpura developed after a patient consumed a weight-loss product containing green tea.[91] On the other hand, drinking green tea could antagonize the anticoagulant effects of warfarin because green tea contains vitamin K.[92]

The half-life for EGCG in one study was between 1.9 and 4.6 hours[93] and in another study was observed to be between 2.2 and 3.4 hours.[94] Based on pharmacokinetic data and possible antiplatelet activity, green tea should be discontinued at least 7 days before surgery.

KAVA

Kava is derived from the dried root of the pepper plant *Piper methysticum*. Kava has gained widespread popularity as an anxiolytic and sedative. The kavalactones appear to be the source of kava's pharmacologic activity.[95]

Because of its psychomotor effects, kava was one of the first herbal medications expected to interact with anesthetics. The kavalactones can have many effects such as: (1) dose-dependent effects on the central nervous system, including antiepileptic, neuroprotective, and local anesthetic properties; (2) act as a sedative-hypnotic by potentiating inhibitory neurotransmission of γ-aminobutyric acid (GABA); (3) increased barbiturate sleep time in laboratory animals,[96] which might explain the mechanism of a coma attributed to an alprazolam-kava interaction[97]; (4) abuse potential, whether long-term use can result in addiction, tolerance, and acute withdrawal after abstinence is unknown; (5) increased γ-glutamyl transpeptidase levels with potential risk of hepatotoxicity[98]; and (6) produces "kava dermopathy," characterized by reversible scaly cutaneous eruptions.[99]

In an in vitro investigation, a kava compound (+)-kavain suppressed the aggregation of human platelets. Kava inhibits cyclooxygenase with the potential to decrease renal blood flow and to interfere with platelet aggregation. Consumption of kava has potential cardiovascular effects that could manifest in the perioperative period.[100,101] Although kava has been banned in Europe since 2002, it is available in North America and many countries in the Pacific region. A concentration-based response relationship can occur with hepatotoxicity, even leading to numerous cases of liver transplantation.[102-104]

Peak plasma levels occur 1.8 hours after an oral dose, and the elimination half-life of kavalactones is 9 hours.[105] Unchanged kavalactones and their metabolites undergo renal and fecal elimination.[106] Pharmacokinetic data and the possibility for enhancement of the sedative effects from anesthetics suggest that kava should be discontinued at least 24 hours before surgery. Earlier discontinuation probably should be considered when surgical procedures are expected to compromise hepatic function or blood flow.

SAW PALMETTO

Saw palmetto, which is used by more than 2 million men in the United States to treat symptoms associated with benign prostatic hypertrophy, is of questionable efficacy for this purpose.[107] The major constituents of saw palmetto are fatty acids and their glycerides (i.e., triacylglycerides and monoacylglycerides), carbohydrates, steroids, flavonoids, resin, pigment, tannin, and volatile oil. The pharmacologic activity of saw palmetto has not been attributed to a single compound.

Although the mechanism of action of saw palmetto is not known, multiple mechanisms have been proposed.[108] Saw palmetto extract, like finasteride, inhibits 5α-reductase in vitro; however, results of in vivo studies have been inconsistent.[109] Other proposed mechanisms are inhibition of estrogen and androgen receptors, binding of autonomic receptors, blocking of prolactin receptor signal transduction, interference with fibroblast proliferation, induction of apoptosis, inhibition of α_1-adrenergic receptors, and antiinflammatory effects.

In a patient undergoing craniotomy, saw palmetto was associated with excessive intraoperative bleeding that required termination of the procedure.[109] Another case of hematuria and coagulopathy in a patient who used saw palmetto was reported.[110] This complication was attributed to saw palmetto's antiinflammatory effects, specifically the inhibition of cyclooxygenase and subsequent platelet dysfunction. Because there are no pharmacokinetic or clinical data for saw palmetto, specific recommendations for preoperative discontinuation cannot be made.

ST. JOHN'S WORT

St. John's wort is the common name for *Hypericum perforatum,* and has been used for mental health and depression conditions. A multicenter clinical trial concluded that St. John's wort is not effective in the treatment of major depression.[111] The compounds believed to be responsible for its pharmacologic activity are hypericin and hyperforin.[112] Commercial preparations are often standardized to a fixed hypericin content of 0.3%.

St. John's wort exerts its effects by inhibiting reuptake of serotonin, norepinephrine, and dopamine.[113] Concomitant use of this herb with or without serotonin reuptake inhibitors can create a syndrome of central serotonin excess.[114] Although early in vitro data implicated monoamine oxidase inhibition as a possible mechanism of action, a number of later investigations have demonstrated that monoamine oxidase inhibition is insignificant in vivo.[115]

Use of St. John's wort can significantly increase the metabolism of many concomitantly administered drugs, some of which are vital to the perioperative care of certain patients. There is induction of the cytochrome P450 3A4 isoform,[116] and interactions with substrates of the 3A4 isoform, including indinavir sulfate,[117] ethinylestradiol,[118] and cyclosporine,[119] have been documented. There are important clinical consequences of this metabolic effect, particularly in transplant patients. In two case reports of heart transplant patients, after taking St. John's wort the patients' plasma cyclosporine concentrations became subtherapeutic and acute transplant rejection resulted. After stopping St. John's wort, plasma cyclosporine remained within the therapeutic range with no further episodes of rejection (Fig. 33.1).[120] In one series of 45 organ transplant patients, St. John's wort was associated with an average 49% decrease in blood cyclosporine levels.[121] Other P450 3A4 substrates commonly used in the perioperative period include alfentanil, midazolam, lidocaine, calcium channel blockers, and 5-hydroxytryptamine receptor antagonists. In addition, the cytochrome P450 2C9 isoform also may be induced, which results in decreased anticoagulant effect of warfarin, a substrate of the 2C9 isoform, in seven reported cases.[118] Other 2C9 substrates include the nonsteroidal antiinflammatory drugs. Furthermore, the enzyme induction caused by St. John's wort may be more pronounced when other enzyme inducers, which could include other herbal medications, are taken concomitantly. St. John's wort also affects digoxin pharmacokinetics.[115]

The single-dose and steady-state pharmacokinetics of hypericin, pseudohypericin, and hyperforin have been determined in humans.[122,123] After oral administration, peak plasma levels of hypericin and hyperforin are achieved in 6.0 and 3.5 hours, respectively, and their median elimination half-lives are 43.1 and 9.0 hours, respectively. Long half-life and altered metabolism of many drugs make concomitant use of St. John's wort a particular risk in the perioperative setting. Pharmacokinetic data suggest that this herbal medication should be discontinued at least 5 days before surgery. Discontinuation is especially important in patients awaiting organ transplantation or in those who might require oral anticoagulation postoperatively. Moreover, these patients should be advised to avoid taking St. John's wort postoperatively.

VALERIAN

Valerian *(Valeriana officinalis)* is an herb that is native to temperate regions of the Americas, Europe, and Asia. It is used as a sedative, particularly in the treatment of insomnia, and virtually all herbal sleep aids contain valerian.[124] Valerian contains many compounds acting synergistically, but the sesquiterpenes are the primary source of valerian's pharmacologic effects. Commercially available preparations may be standardized to valerenic acid.

Valerian produces dose-dependent sedation and hypnosis.[125] These effects are probably mediated through modulation of GABA neurotransmission and receptor function.[126] Valerian increased barbiturate sleep time in experimental animals.[127] In several randomized, placebo-controlled trials in humans, there was a mild subjective improvement in sleep with valerian, especially when used for 2 weeks or more.[128,129] Objective tests have had less consistent results, with little or no improvement in sleep noted.[130] In one patient, valerian withdrawal appeared to mimic an acute benzodiazepine withdrawal syndrome characterized by

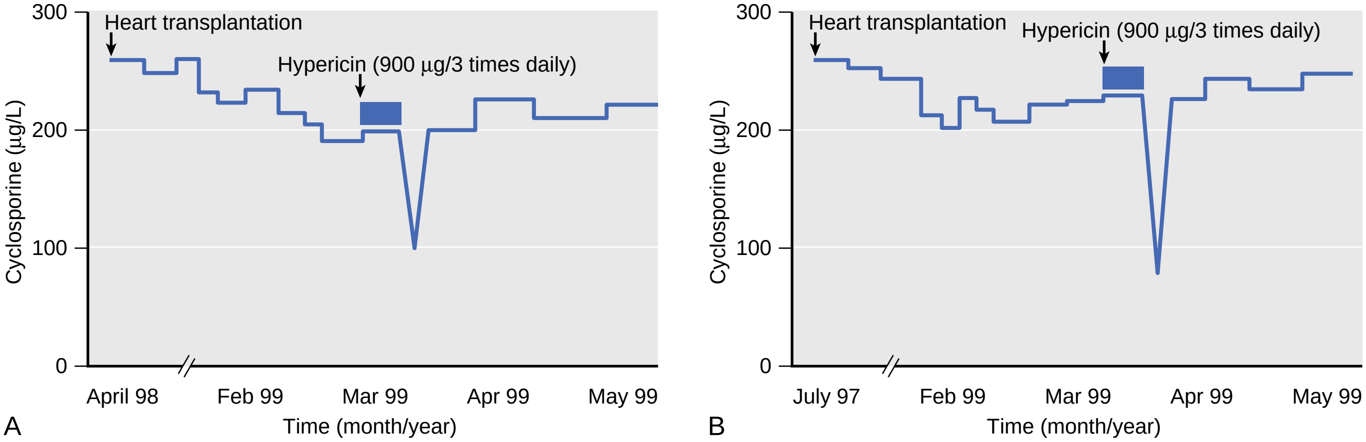

Fig. 33.1 **Cyclosporine concentrations in two patients (A and B) after heart transplantation. Treatment with St. John's wort extract containing 900 µg of hypericin was associated with a drop in cyclosporine values below the therapeutic range and acute transplant rejection.** (From Breidenbach T, Hoffmann MW, Becker T, et al. Drug interaction of St John's wort with cyclosporine. *Lancet*. 2000;355:1912.)

delirium, cardiac complications after surgery, and attenuation of the symptoms by administration of a benzodiazepine.[131] Based on these findings, valerian should potentiate the sedative effects of anesthetics and adjuvants that act at the GABA receptor, such as midazolam.

The pharmacokinetics of valerian's constituents have not been studied, although their effects may be short-lived. Abrupt discontinuation in patients who may be physically dependent on valerian risks benzodiazepine-like withdrawal. In these individuals, this herbal medication should be gradually decreased with close medical supervision over the course of several weeks before surgery. If such tapering is not feasible, physicians can advise patients to continue taking valerian until the day of surgery. Based on the mechanism of action and a reported case of efficacy,[131] benzodiazepines can treat withdrawal symptoms should they develop in the postoperative period.

OTHER HERBAL MEDICINES

In a survey conducted in 2007,[1] the top 10 herbal medicines also included soy isoflavones, grape seed extract, and milk thistle. There are no reports of adverse effects or perioperative risks from these herbs.

Although boldo *(Peumus boldus)*, Danshen *(Salvia miltiorrhiza)*, Dong quai *(Angelica sinensis)*, and papaya *(Carica papaya)* are encountered less frequently, it may be prudent to discontinue their use 2 weeks before surgery because they have shown antiplatelet aggregation activity and herb-drug interactions.[132]

COMMON DIETARY SUPPLEMENTS

Herbal medicines fall into the broader category of dietary supplements that also includes vitamins, minerals, amino acids, enzymes, animal extracts, prebiotics, and probiotics. Data on the safety of these agents in the perioperative period are scant. High-dose vitamin use, particularly of the fat-soluble vitamins (i.e., A, D, E, and K), can be associated with acute and chronic toxicity. Drug interactions for coenzyme Q_{10}, glucosamine, chondroitin, sulphate, and fish oil have been sufficiently documented to merit inclusion in this chapter. Prebiotics and probiotics have become increasingly popular in research, in the context of the rapidly evolving field of gut microbiome, adding to the current knowledge of perioperative medicine.

Coenzyme Q_{10}

Coenzyme Q_{10} (CoQ_{10}), or ubidecarenone, is a single-constituent antioxidant compound that is structurally related to vitamin K. It is widely promoted as an antioxidant. Endogenous CoQ_{10} can prevent the membrane transition pore from opening, because it counteracts several apoptotic events, such as DNA fragmentation, cytochrome c release, and membrane potential depolarization.[52]

Of importance, this compound interacts with warfarin and was investigated in rats.[133] Following oral administration of 1.5 mg/kg of racemic warfarin to rats during an 8-day oral regimen of CoQ_{10} (10 mg/kg daily), no apparent effect was observed on serum protein binding of warfarin enantiomers. Treatment with CoQ_{10} did not affect the absorption and distribution of the S- and R-enantiomers of warfarin, but it increased total serum clearance of both R- and S-warfarin. The increased clearance values are likely due to acceleration of certain metabolic pathways and renal excretion of the warfarin enantiomers.

An in vitro study showed a predicted 32% and 17% increase in the total clearance of S- and R-warfarin respectively with co-administration of 100 mg CoQ_{10}.[134] CoQ_{10} may decrease the effects of warfarin,[135] but results were inconsistent in another controlled, clinical trial.[136] In 171 patients, co-administration of CoQ_{10} with warfarin appeared to increase the risk of bleeding.[137] Based on the clinical information regarding drug interaction and reported prolonged elimination half-life (38-92 hours) after a single oral dose,[138] CoQ_{10} should be discontinued at least 2 weeks before surgery.

GLUCOSAMINE AND CHONDROITIN SULFATE

Glucosamine and chondroitin sulfate are widely used for joint disorders by many patients undergoing orthopedic procedures. Although their mode of action may be complex, glucosamine and chondroitin sulfate have been widely accepted as supplements in the management of osteoarthritis (OA) because they are the essential components of proteoglycan in normal cartilage.[139] When a large-scale trial evaluated glucosamine and chondroitin sulfate alone or in combination, pain was not reduced in a group of patients with OA of the knee. Exploratory analyses suggested that the two in combination might be effective in a subgroup of patients with moderate-to-severe knee pain.[140]

Long-term clinical data regarding the safety of glucosamine and chondroitin sulfate alone or in combination are limited. Use of chondroitin sulfate alone is well tolerated and without significant adverse drug interaction.[139] One concern regarding the use of glucosamine is its potential to cause or worsen diabetes in animal models[141]; this effect is supported by clinical studies.[142] In a report from the FDA MedWatch database, there were 20 cases of complications involving glucosamine or glucosamine-chondroitin sulfate use with warfarin. Coagulation was altered as manifested by increased INR or increased bleeding or bruising.[143]

When glucosamine is taken orally, 90% is absorbed. Because of extensive first-pass metabolism, only 25% bioavailability is achieved by oral administration compared with bioactivity of 96% with intravenous administration.[144] Peak plasma levels occurred 4 hours after an oral dose and declined to baseline after about 48 hours.[145] Chondroitin sulfate was absorbed slowly after oral ingestion with a plasma peak at 8.7 hours and decline to baseline at about 24 hours.[146] Considering the reported interaction between glucosamine-chondroitin and warfarin, these supplements should be discontinued 2 weeks before surgery, especially if warfarin will be given during the perioperative period.

FISH OIL

Intake of fish oil supplements containing omega-3 fatty acids (eicosapentaenoic acid and docosahexaenoic acid) reduces the incidence of many chronic diseases that involve inflammatory processes, including cardiovascular diseases, inflammatory bowel disease, cancer, rheumatoid arthritis, and neurodegenerative illnesses.[147] However, omega-3 fatty acid did not reduce the rate of death in patients with cardiovascular risk in one study.[148] A metaanalysis of efficacy also concluded that omega-3 polyunsaturated fatty acid supplementation does not decrease the risk of all-cause mortality, cardiac death, sudden death, myocardial infarction, or stroke based on relative and absolute measures of association.[149] This article included many studies of patients with complex risk factors.

Omega-3 fatty acids, however, can inhibit platelet aggregation and increase bleeding risk by the following studies: (1) In vitro experiments have demonstrated an antiplatelet aggregate effect,[150] and inhibition correlated with platelet cyclic adenosine monophosphate levels.[151] (2) In vivo studies have showed decreased platelet aggregation but do not influence bleeding time.[152,153] (3) The inhibition of platelet aggregation was gender specific in a clinical study.[154]

Although evidence for significant bleeding concerns is not found in clinical trials,[155,156] several case reports have illustrated a possible interaction between warfarin and omega-3 fatty acids.[157] Extremely elevated INR associated with warfarin in combination with omega-3 fatty acids was found in two cases.[158,159] These reports suggest that fish oil be discontinued 2 weeks before surgery, especially for patients taking large doses.

PREBIOTICS AND PROBIOTICS

A prebiotic is a nondigestible food ingredient that beneficially affects the host by selectively stimulating the growth and activity of one or a limited number of bacteria in the colon that has the potential to improve host health. A probiotic is a live microbial feed supplement that beneficially affects the host by improving its intestinal microbial balance.[159a] Both prebiotics and probiotics can perturbate the gut microbiota, a consortium of diverse microorganisms residing in the gastrointestinal tract, with significant influence in energy metabolism, immune system development, neurologic function, and behaviors. Research on gut microbiota has made significant progress in recent years owing to the technological advancement of next-generation DNA sequencing and high-throughput data processing.

Targeting gut microbiota using fecal transplantation or fecal capsules to treat recurrent *Clostrisium difficile* infection is under intense investigation, with a few trials indicating promising results.[159b] However, a recent trial comparing oral probiotics with oral antibiotics for elective colorectal surgery showed that conventional oral antibiotics preparation in addition to mechanical bowel preparation is better than oral probiotics with mechanical bowel preparation.[159c] Studies have implicated gut microbiota in visceral hypersensitivity (irritable bowel syndrome), inflammatory pain, and more recently, neuropathic pain.[159d-159f] Moreover, gut microbiota have been shown to modulate the central nervous system function, including anxiety/depression and cognition. Despite the rapidly evolving field of gut microbiome, data on perioperative use of prebiotics and probiotics are scarce. Future research is warranted to investigate potential roles of prebiotics and probiotics in the perioperative setting, particularly in volatile anesthetics sensitivity, postoperative pain control, and postoperative cognitive dysfunction.

Other Dietary Supplements

Other top 10 dietary supplements include flaxseed oil, fiber or psyllium, cranberry, melatonin, methylsulfonylmethane, and lutein.[1] No special concerns have been published associated with bleeding or other perioperative risks from the use of these supplements.

Summary

Commonly used herbal medications can have direct and indirect effects in the perioperative period. Although there is little direct evidence for discontinuation timing, emerging knowledge of the underlying biology of these medications and review of case reports suggest that herbal medications should be considered in the perioperative plan.

Acupuncture

MECHANISM AND GENERAL PRACTICE

Although acupuncture can reduce preoperative anxiolysis, intraoperative anesthetic requirements, and postoperative ileus, and can support cardiovascular function, it has been most widely studied to control postoperative pain and to prevent or treat nausea and vomiting.[160]

Acupuncture has been used in China for more than 3000 years, and in the 1970s, it gained international attention as a treatment for a variety of diseases. In 1974, Dr. Bonica became the first pain physician invited by the Chinese government as a member of an American medical delegation to assess the utility of acupuncture in surgical procedures. He witnessed more than 28 surgeries personally and spoke with a large number of surgeons as well as anesthesia providers. In the report subsequently published in JAMA,[160a] he pointed out, “it (acupuncture) may prove extremely useful in relieving postoperative pain thus obviating the depressant effects of narcotics usually employed for this purpose.” Traditional Chinese medicine (TCM) is the basis for acupuncture practice. According to TCM, the human body operates on 12 bilaterally distributed channels (6 yin channels and 6 yang channels) in conjunction with two midline channels in the ventral and dorsal aspects of the body, respectively. Acupuncture is the stimulation of anatomic locations on the skin by a variety of techniques that can be classified as invasive (e.g., needles, injections) or noninvasive (e.g., transcutaneous electrical stimulation, pressure, laser). Needles inserted into the skin can be stimulated by manual manipulation, moxibustion (i.e., burning a substance to produce heat), pressure, laser, and electricity. A scientific basis may exist for acupuncture. Acupuncture stimulates high-threshold, small-diameter nerves that activate the spinal cord, brainstem (i.e., periaqueductal gray area), and hypothalamic (i.e., arcuate) neurons, which trigger endogenous opioid mechanisms.[161] The effect of acupuncture analgesia can be reversed by administration of naloxone.[162] Other mechanisms such as modulation of immune function,[163] inhibition of the inflammatory response,[164] regulation of neuropeptide gene expression,[165] and alteration in hormonal levels[166] have been proposed. The development of neuroimaging tools, such as positron emission tomography[167] and functional magnetic resonance imaging (fMRI),[168,169] make noninvasive studies of acupuncture's effects on human brain activity possible. Studies using positron emission tomography have demonstrated that the thalamic asymmetry present in patients suffering from chronic pain was reduced after acupuncture treatment. Other studies using fMRI have pointed to relationships between particular acupoints and activation of the visual cortex.[170] Using a noninvasive imaging technique called Bi-Digital O-Ring Test, researchers found that each meridian is connected to a representative area in the cerebral cortex, suggesting that the meridian system defined in the theories of Chinese medicine may overlap with distinct supraspinal regions.[170a] Electroacupuncture, particularly at low frequency, is associated with widespread fMRI signal increases in the anterior insula area, limb, and paralimbic structures. These humoral and neuronal changes induced by acupuncture form the basis for its clinical use.

According to the Centers for Disease Control and Prevention, more than 50 million procedures are performed each year in the United States, including more than 1 million hip and knee replacements. Most surgical procedures are associated with postoperative pain, for which opioids are the mainstay of treatment. However, opioid usage is associated with a high incidence of side effects including respiratory depression, reduced gastrointestinal motility, sedation, and itching. Chronic exposure to high-dose opioids can also induce opioid tolerance and dependence. It is therefore highly desirable to develop alternative therapies that provide adequate postoperative pain relief with minimal side effects. In this context, acupuncture for acute postoperative pain control has gained significant interest, including its use for oral-maxillofacial and neck surgeries, sternotomy/thoracotomy, abdominal/pelvic surgeries, and orthopedic and spine surgeries. Studies have shown that acupuncture can lead to improved pain scores or reduced opioid requirements postoperatively. Lao and associates carried out a randomized, double-blinded, and placebo-controlled trial on postoperative dental pain ($N = 39$).[170b] The acupuncture group received acupuncture for about 20 minutes with intermittent manual manipulation to trigger "De Qi" sensation—a sensation of numbness, distension, or electrical tingling at the needling site. The control group underwent placebo acupuncture treatment at the identical acupuncture points to the acupuncture group but without needle insertion into the skin. Mean pain-free postoperative time was significantly longer in the acupuncture group (172.9 minutes) than in the placebo group (93.8 minutes). Pain medication requirements were significantly less in the acupuncture group than in the control group. Of note, this study also ruled out psychological variables as confounders for their observed benefits of acupuncture.

It is important to note that many of the studies on clinical applications of acupuncture have insufficient sample size, high dropout rates, inadequate follow-up, and poorly defined illnesses, enrollment criteria, and outcome measures.[161] Additionally, many of the clinical trials are single center studies, which could potentially demonstrate larger treatment effects than multicenter studies.[170c]

Side effects of acupuncture treatments include bruising or bleeding at the needle insertion site, transient vasovagal response, infection, dermatitis, and retained needle fragments. The occurrence of adverse events during acupuncture treatment is considered extremely low. In a survey that included 34,407 acupuncture treatments, there were no reported events of serious side effects and only 43 cases of significant mild side effects were noted, such as nausea, fainting, and bruising.[170d,e] Recently, the safety of acupuncture was confirmed in a cohort of cancer patients with thrombocytopenia.[170f]

ACUPUNCTURE FOR POSTOPERATIVE NAUSEA AND VOMITING

One of the most promising indications for acupuncture is to prevent postoperative nausea and vomiting (PONV). PONV results in patient dissatisfaction, delayed discharge, unanticipated hospital admission, and the use of resources. Drugs have been the mainstay of management, however these have limited effectiveness, are associated with adverse effects, and can be costly. Acupuncture prevents PONV compared with sham acupuncture or no treatment.[160] In two early controlled trials, acupuncture prevented PONV in the pediatric population[171,172]; however, one literature review of 10 research studies examining the use of acupressure and acupuncture in adults concluded that it is not effective in preventing and managing PONV.[173] Other clinical studies have found that acupuncture prevents PONV and results in a greater degree of adult patient satisfaction.[174,175] For many of the trials in both adults and children, the PONV acupuncture point was P6 or PC6 (i.e., Nei guan or Pericardium 6).[173,176] The P6 acupuncture point is located between the palmaris longus and flexor carpi radialis muscle tendons, 4 cm proximal to the distal wrist crease and 1 cm below the skin (Fig. 33.2). Intraoperative stimulation of the P6 acupuncture point reduced the incidence of PONV, and its efficacy was similar to that of antiemetic drugs.[177] Stimulation of the acupuncture point should be initiated before induction of anesthesia.[178] Postoperative stimulation may be just as or more effective.[179] In children, stimulation immediately before emergence and in the recovery room has been effective. A recent metaanalysis for pediatric tonsillectomy indicated that acupuncture at the P6 acupuncture point is effective in preventing PONV.[179a] Some anesthesiologists anecdotally report tapping a small needle cap or other piece of smooth plastic over the P6 point as an effective means of acupressure stimulation.

Studies often differ in acupuncture method: duration and timing of stimulation, unilateral versus bilateral stimulation, and type of stimulation (i.e., needles with or without additional stimulation, acupressure, transcutaneous electrical stimulation, cutaneous laser stimulation, injection of a 50% dextrose solution, or capsicum plaster). Data to compare the effectiveness, safety, and costs of different methods of stimulation are inadequate.

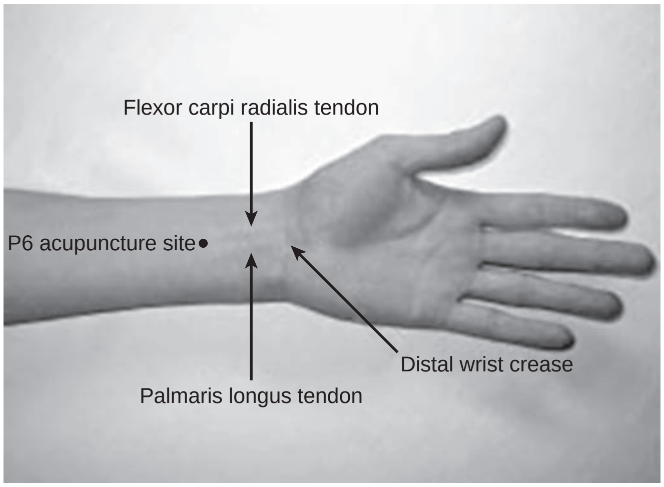

Fig. 33.2 The P6 acupuncture point is located between the palmaris longus and flexor carpi radialis muscle tendons, 4 cm proximal to the distal wrist crease and 1 cm below the skin.

DEEP BREATHING

Deep breathing exercises are performed as part of a relaxation technique. With this method, a subject consciously slows breathing and focuses on taking deep breaths.[180] Deep breathing can help reduce abdominal and surgical pain.[181,182]

Studies of postoperative pain relief with breath control were reported in the 1970s.[183,184] Since then, many studies have reported its efficacy against postoperative pain in adult patients[181,185]; prevented postoperative pulmonary complications[186]; and decreased pain in pediatric patients.[199]

Fast or forced deep breathing can also increase postoperative pain.[187] Thus, those who assist patients in postoperative pain management should encourage deep breathing exercises that are performed slowly, smoothly, and gently. Slow, deep breathing relaxation exercises have been used successfully as an adjunct to opioids for postoperative pain management in patients who had coronary bypass surgery[188]; however, after abdominal surgery, deep breathing was ineffective for pain reduction in older patients because pulmonary complications developed postoperatively.[189] Most patients who receive deep breathing education think it is useful, and the exercise was effective in increasing their feelings of rapport with staff and intention to follow their doctor's directives.[190] Results from a recent trial demonstrated that slow, deep breathing had analgesic effects with increased vagal cardiac activity.[191] Slow, deep breathing relaxation can also decrease the sensation of postoperative nausea.[192,193]

Music Therapy

Music therapy is the clinical, evidence-based use of music interventions to accomplish individualized therapeutic goals. Because music can be used for diverse applications, music therapists practice in a variety of healthcare and education settings.[194] Music for pain relief benefits individuals experiencing a low to moderate amount of pain more than those experiencing a high degree of pain.[195] A patient's preferred music should be considered when it is used for pain relief. The increase of endogenous opioids through music may be the reason for pain relief.[194]

Perioperatively, music can decrease preoperative anxiety, reduce intraoperative sedative and analgesic requirements, and increase patient satisfaction. Patient-selected music can reduce patient-controlled sedative requirements during spinal anesthesia and analgesic requirements during lithotripsy.[196] Music in the preoperative setting can reduce anxiety without affecting physiologic measures of stress.[197,198] Music can also increase patient satisfaction and reduce systolic blood pressure during cataract surgery after retrobulbar block.[199] Perioperative music can reduce arterial pressure, anxiety, and pain among women undergoing mastectomy for breast cancer.[200] As a noninvasive intervention, the low sensory stimulation of music reduced anxiety and increased cooperation in children undergoing induction of anesthesia.[201]

Music therapy interventions that have targeted nausea, both anticipatory or after treatment, have had conflicting results.[194] One study showed that a patient's preferred music for listening during chemotherapy infusion was effective in decreasing the onset and occasion of nausea.[202] In another study, listening to music with a personal message from the physician yielded no difference in chemotherapy-induced side effects compared with not listening to music during chemotherapy.[203] Some studies have found no effect on PONV from music therapy,[204,205] yet PONV was reduced in hospitalized transplant patients postoperatively.[206] Although the exact mechanism is not well understood, music therapy has been an alternative option to mainstream therapies in healthcare settings to reduce patient pain, anxiety, and perioperative stress.[207] Another use of music is in the intensive care unit. A recent clinical trial observed that among patients in the intensive care unit who received acute ventilator support for respiratory failure, patient-directed music intervention resulted in more reduction in anxiety and sedation frequency and intensity compared with usual care.[208] In addition, music can attenuate cardiovascular variability and nociceptive effects.[209,210]

Conclusion

One of the fastest changing aspects of health care is the growing public and scientific interest in CAM. An increasing number of patients and physicians have combined integrative medicine into their treatment plans. Because of the significant increase in demand for CAM therapies, most U.S. medical schools have added coursework on integrative medicine. Anesthesiologists are the physicians to manage these patients perioperatively, and therefore should have updated knowledge for the modalities of complementary and integrative medicine. To manage herbal medications in the perioperative period, their possible direct and indirect effects should be recognized based on an understanding of the underlying pharmacology. Surgery and anesthesia can usually proceed safely if potential complications are anticipated and can be minimized. As CAM therapies

gain popularity in the United States, patients are likely to accept some alternative modalities during the perioperative period, such as acupuncture, deep breathing, and musical intervention. These modalities are easy to administer, have a rapid onset of action, are cost effective, and produce minimal side effects. Based on preliminary studies, perioperative use of CAM therapies may be an adjunct for management of multiple symptoms including pain, anxiety, and nausea and vomiting, among others. Additional large, well-designed trials are required to verify current observations on the effectiveness of CAM and to answer the concerns of possible side effects. Although medical schools are beginning to incorporate CAM into their curricula, it is important for anesthesiologists to stay informed about CAM therapies (Table 33.2).

Acknowledgment

The editors and publisher would like to thank Drs. Chong-Zhi Wang, Chun-Su Yuan, and Jonathan Moss for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Patient Positioning and Associated Risks

KRISTINE E.W. BREYER and STEVEN ROTH

KEY POINTS

- Patient positioning is a major responsibility that requires the cooperation of the entire surgical team.
- Many patient positions that are used for surgery result in undesirable physiologic consequences including significant cardiovascular and respiratory compromise. Anesthetic agents blunt natural compensatory mechanisms, rendering surgical patients vulnerable to positional changes.
- Peripheral nerve injuries, although rare, represent 22% of cases in the 1990 to 2007 American Society of Anesthesiologists' Closed Claims Project. The mechanisms of injury are stretching, compression, and ischemia. Patient positioning is often a suspected contributory factor, although precautions have usually been taken and no specific cause for the injury is known.
- The American Society of Anesthesiologists first issued a Practice Advisory in 2000 for the prevention of perioperative peripheral neuropathies that was updated in 2019. However, very few of the studies reviewed met the standard for a scientifically proven relationship between intervention and outcome.
- Anesthesia administered outside the operating room presents special challenges with regard to patient positioning because of monitoring and equipment limitations and differences in the work environment and culture.
- Perioperative visual loss (POVL) is a rare but serious injury that appears more frequently after cardiac, spine, and orthopedic joint surgery.
- Causes of POVL include central or branch retinal artery occlusion, anterior and posterior ischemic optic neuropathy, cortical blindness, acute glaucoma, and acute expansion of gas bubbles placed in the eye in retinal surgery.
- Signs and symptoms of visual loss in the postoperative period may be subtle and can be incorrectly attributed to the residual effects of anesthetic drugs. Any patient reporting eye pain, an inability to perceive light or motion, complete or partial loss of visual fields, decreased visual acuity, or loss of pupil reactivity must be evaluated immediately by an ophthalmologist.
- The most common cause of perioperative central and branch retinal artery occlusion is compression of the eye. During cardiac surgery, emboli may occlude the retinal arteries.
- Patients who undergo prolonged operative procedures in the prone position with large blood loss are at increased risk for development of ischemic optic neuropathy. Other factors conferring a risk during spine surgery include male sex, obesity, the use of a Wilson frame, and intravascular fluids administered perioperatively.
- Patients should be informed of the risk for visual loss accompanying lengthy surgical procedures with the patient positioned prone and with anticipated large blood loss. Both anesthesia and surgery personnel, together, should develop a plan by which informed consent for this complication may be facilitated.
- POVL in the presence of focal neurologic signs or the loss of accommodation reflexes or abnormal eye movements suggests a diagnosis of cortical blindness. Neurologic consultation should be obtained.

Introduction

The purpose of patient positioning in the operating room is to facilitate the surgical procedure, however, optimal surgical positioning may put patients at risk of injury or significantly alter intraoperative physiology. Peripheral nerve injuries, pressure injuries, and eye injuries are significant sources of perioperative morbidity.[1-3] Proper patient positioning is imperative and requires the cooperation of the entire surgical team. For this reason the American Society of Anesthesiologists (ASA) requires intraoperative documentation of "patient positioning and actions to reduce the chance of adverse patient effects or complications related to positioning."[4] Preventing positioning complications requires clinical judgement, vigilance, and a cooperative team approach. This chapter will review the most commonly utilized surgical positions, physiologic alterations from positioning, and specific risks and injuries associated with different surgical positions.

Physiologic Considerations of Positioning

Complex physiologic responses have evolved to blunt the hemodynamic effects of positional changes in order to maintain blood pressure within a narrow range. These essential mechanisms maintain perfusion to the brain and vital organs, regardless of posture and position—for example, as a person reclines from an upright to a supine position venous return to the heart increases and initially the increased preload causes an increase in stroke volume and cardiac output. This causes an increase in arterial blood pressure, which activates afferent baroreceptors from the aorta (via the vagus nerve) and within the walls of the carotid sinuses (via the glossopharyngeal nerve). Mechanoreceptors from the atria and ventricles are also activated to decrease sympathetic outflow to muscle and splanchnic vascular beds. Lastly, atrial reflexes are activated to regulate renal sympathetic nerve activity, plasma renin, atrial natriuretic peptide, and arginine vasopressin levels.[5] Ultimately, heart rate and cardiac output are decreased to reach homeostasis in the new position.

Different types of anesthesia and anesthetic agents can blunt these compensatory pathways. Most current inhaled anesthetics, and many intravenous anesthetics, induce vasodilation. The use of spinal or epidural anesthesia causes a significant sympathectomy across all anesthetized dermatomes, independent of the presence of general anesthesia, reducing preload and potentially blunting cardiac response. Therefore, under anesthesia, changes in patient position may cause a more exaggerated hemodynamic response compared with position changes in unanesthetized patients. This can be particularly important for positions that would normally elicit a sympathetic response and vasoconstriction in order to maintain cardiac and cerebral perfusion, such as the sitting position. Interruptions in monitoring to facilitate positioning or turning of the surgical table should be minimized during position changes in order to monitor hemodynamic outcomes. Being aware of the physiologic consequences will help the anesthesiologist anticipate changes in hemodynamics with patient position changes.

Positive-pressure ventilation increases mean intrathoracic pressure, diminishing the venous pressure gradient from peripheral capillaries to the right atrium. This can affect cardiac output as the normal pressure gradients for venous circulation and cardiac preload are relatively low.[6] Positive end-expiratory pressure further increases mean intrathoracic pressure, and possibly further compromises venous return and cardiac output, as do conditions associated with low lung compliance, such as airways disease, obesity, ascites, and light anesthesia.[7] The anesthesia provider needs to anticipate, monitor, and treat these effects, as well as assess the safety of positional changes for each patient.

Normal spontaneous ventilation results from relatively small negative intrathoracic pressure shifts because of diaphragmatic displacement and chest wall movement. Resultant negative intrathoracic pressure also promotes venous return to the heart by reducing the pressure in the great veins and right atrium.[8] With spontaneous ventilation, diaphragmatic movement is greatest adjacent to the most dependent portions of the lung, helping bring new ventilation to the zones of the lung that are preferentially perfused. When a person shifts from standing to a supine position, functional residual capacity decreases in part due to cephalad displacement of the diaphragm. The chest wall contributes less to ventilation in the supine position causing more reliance on diaphragm contribution. Although gravity has some effect on the perfusion and ventilation of the lung, new evidence points to the importance of other factors as well.[9-13]

Under general anesthesia spontaneously breathing patients have reduced tidal volumes, reduced functional residual capacity, and increased closing volumes. This leads to more ventilation perfusion mismatching due to increased atelectasis and a reduced minute ventilation. Using positive-pressure ventilation with muscle relaxation may counter some of the ventilation-perfusion mismatch by ensuring adequate minute ventilation and limiting atelectasis by use of positive end-expiratory pressure.[9] In addition to these effects of anesthesia, patient position has distinct effects on pulmonary function. In particular, any position that limits the movement of the diaphragm, chest wall, or abdomen may increase atelectasis and therefore increase intrapulmonary shunt.

Newer investigations using high-resolution imaging have shown the prone position to provide superior ventilation-perfusion matching in the posterior segments of the lung near the diaphragm when compared with the supine position. Ventilation of these posterior segments is enhanced, while blood flow is maintained, despite their nondependent position.[8,14]

General Positioning Considerations

Coordination of the multidisciplinary surgical team is required in order to achieve proper and safe positioning of patients. Principles include maintaining spine and extremity neutrality as much as possible. The patient should lie on a padded surface, and additional padding should be placed around bony prominences and hard objects, such as intravenous fluid lines, monitoring equipment, and poles.

People who are awake and not sedated change position if they become uncomfortable. Even during normal sleep, some movement is normal in order to prevent pressure or stretch injuries. Anesthetized patients are unable to change position if pressure or stretch causes nociception. Therefore, whenever possible, patients should be placed in a natural position that would be well tolerated if the patient were awake or not sedated. When more extreme positions cannot be avoided, their duration should be limited as much as possible. It is reasonable to ask patients what positions they can tolerate comfortably.

Specific Positions

SUPINE

The most common position for surgery is the supine or dorsal decubitus position (Fig. 34.1). Classically, the head, neck, and spine all retain neutrality. Because the entire body is close to the level of the heart, hemodynamic reserve is well maintained. Tissues overlying all bony prominences,

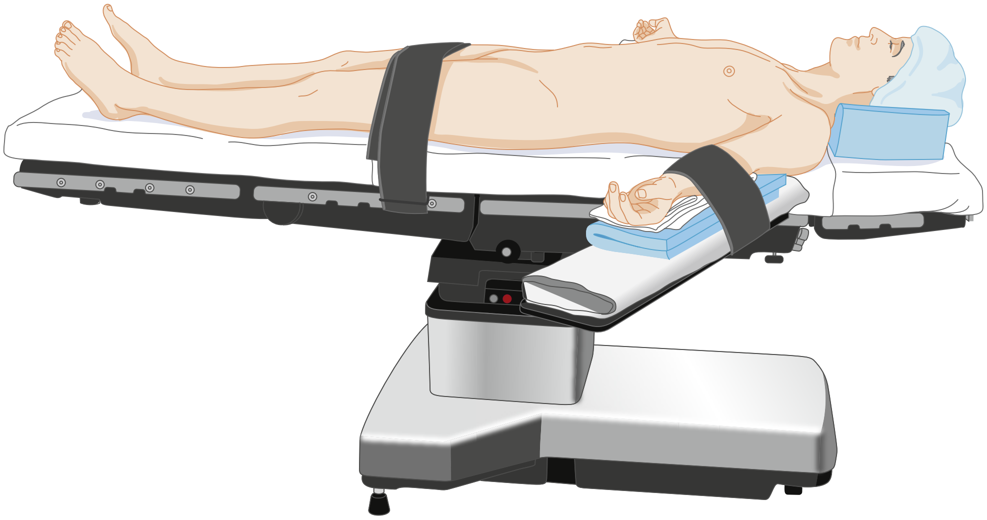

Fig. 34.1 Supine position. The base of the table is asymmetrical. When positioned in the usual direction, the patient's center of gravity is over the base. Weight limits decrease when in reverse orientation to the base.

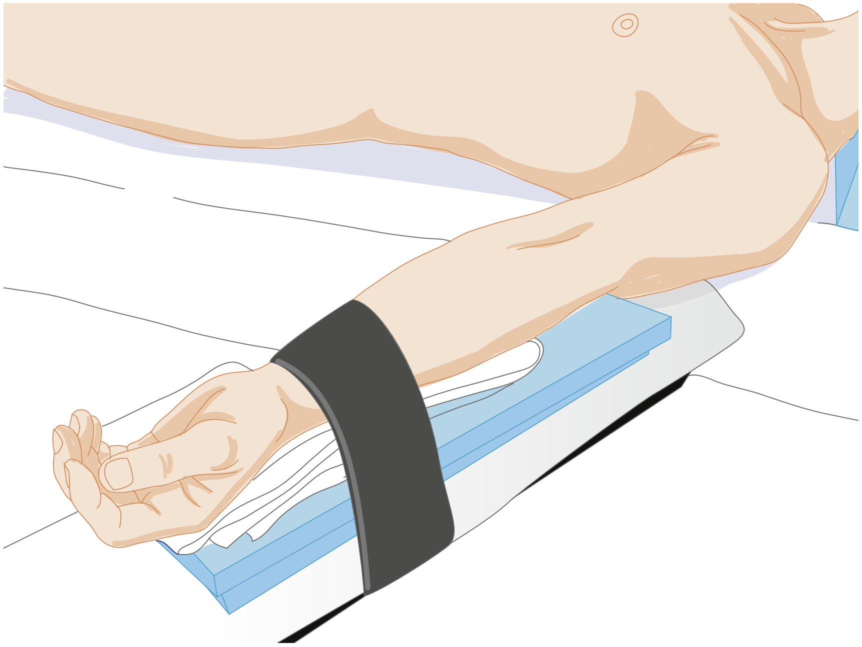

Fig. 34.2 Arm position using the arm board. Abduction of the arm is limited to less than 90 degrees whenever possible. The arm is supinated, and the elbow is padded.

such as the heels and sacrum, must be padded to prevent soft tissue ischemia as a result of pressure, especially during prolonged surgery.[15]

The arms can be abducted, adducted, or one arm abducted and one arm adducted. In any variation, the arms should be placed in as neutral a position as possible, minimizing stretch and over extension.[4] When the arms are adducted, they must remain securely placed next to the body. For abducted arm position, abduction should be limited to less than 90 degrees to minimize the likelihood of brachial plexus injury.[4,16] Hands and forearms can be supinated or kept in a neutral position with the palm toward the body. This also reduces external pressure on the spiral groove of the humerus and the ulnar nerve (Fig. 34.2).[4,17,18] Particular attention should be paid to pad bony prominences, like the elbows, and any protruding objects, such as intravenous fluid lines, monitoring equipment, and poles (Fig. 34.3).

Variations of the Supine Position

Several variations of the supine position are frequently used. These include the lawn (or beach) chair position, frog-leg position, and Trendelenburg and reverse Trendelenburg positions. The lawn chair position (Fig. 34.4) reduces stress on the back, hips, and knees by placing the patient's hips and knees in mild flexion. This position is often better tolerated by patients who are awake or undergoing monitored anesthesia care than the full supine position. The lawn chair position also facilitates lower extremity venous drainage because the legs are placed slightly above the level of the heart. Abdominal wall tension is also reduced because the xiphoid to pubic distance is decreased. Proper positioning involves positioning the patient's hips at the break of the surgical table and avoiding venous pooling in the legs.

The frog-leg position allows procedural access to the perineum, medial thighs, genitalia, and rectum. The patient is positioned supine and then the hips and knees are flexed and the hips are externally rotated with the soles of the feet facing each other. Support of the patient's knees to minimize stress and postoperative pain in the hips is required.

The Trendelenburg position, achieved by tilting a supine patient head down (Fig. 34.5), is linked by name to a 19th-century German surgeon, Friedrich Trendelenburg, who described its use for abdominal surgery. Walter Cannon, a Harvard physiologist, is credited with popularizing the use of Trendelenburg positioning to improve hemodynamics for patients in shock during World War I. Today the Trendelenburg position is frequently utilized to improve exposure during abdominal and laparoscopic surgery, during central line placement to prevent air embolism and distention of the central vein, and to offset hypotension by temporarily increasing venous return. A steep (30-45 degrees) head-down position is now frequently used for robotic prostate and gynecologic surgeries.

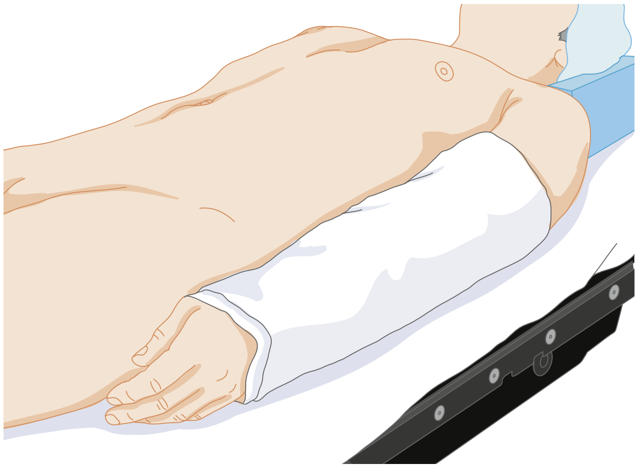

Fig. 34.3 Arm tucked at patient side. The arm is in the neutral position with the palm to the hip. The elbow is padded, and the arm is well supported by the mattress.

For all positions in which the head is at a different level than the heart, the effect of the hydrostatic gradient on cerebral arterial and venous pressures should be considered when estimating cerebral perfusion pressure. Careful documentation of any potential arterial pressure gradient is especially prudent.

The Trendelenburg position does produce hemodynamic and respiratory changes; however, the hemodynamic changes are not as long-lasting as often thought. Initial placement of the patient in head-down supine position will increase cardiac output approximately 9% in less than 1 minute via an autotransfusion from the lower extremities. This effect is not sustained and within approximately 10 minutes the cardiac output begins to return to baseline. Nevertheless, the Trendelenburg position is still considered an essential part of initial resuscitation efforts to treat hypotension and acute hypovolemia.[19] Functional residual capacity is decreased due to gravitational pull of the diaphragm cephalad. Pulmonary compliance is increased by decreased functional residual capacity and is often further decreased in the Trendelenburg position, due to patient-positioning straps across the chest. In a spontaneously breathing patient, the work of breathing increases. In patients under general anesthesia, these pulmonary changes result in higher airway pressures. Changes to the mechanical ventilator settings can compensate for some of the respiratory changes. However, with patient body habitus and variations in positioning, the higher airway pressures, and changes to minute ventilation are too great to safely continue in the steep Trendelenburg position. Testing the position for patient tolerance after anesthetic induction and completed positioning, prior to the initiation of the surgical procedure, is recommended.

Intracranial and intraocular pressures (IOCs) also increase in Trendelenburg position. Trendelenburg is contraindicated in patients with increased intracranial pressures. In fact, for some patients with severe intracranial hypertension, even

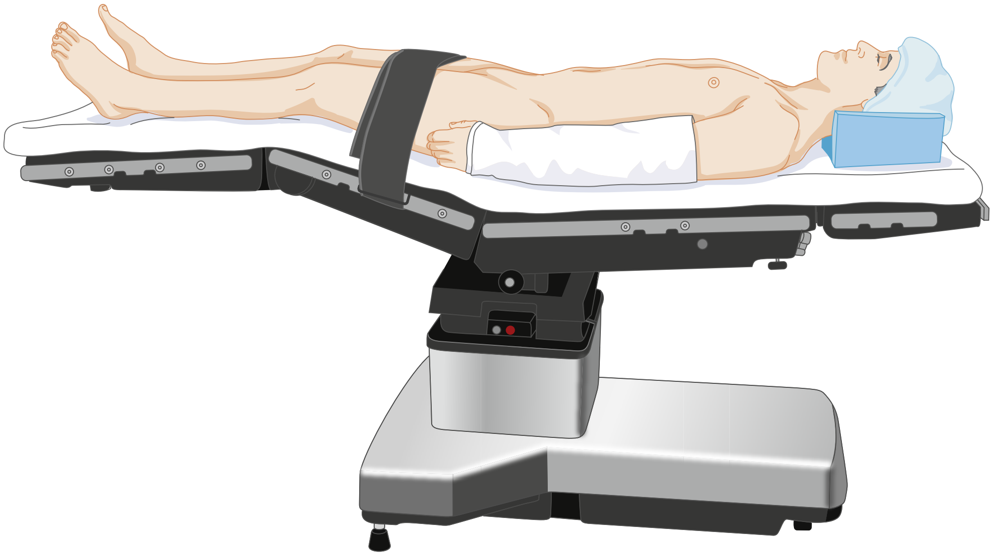

Fig. 34.4 Lawn or beach chair position. Flexion of the hips and knees decreases tension on the back.

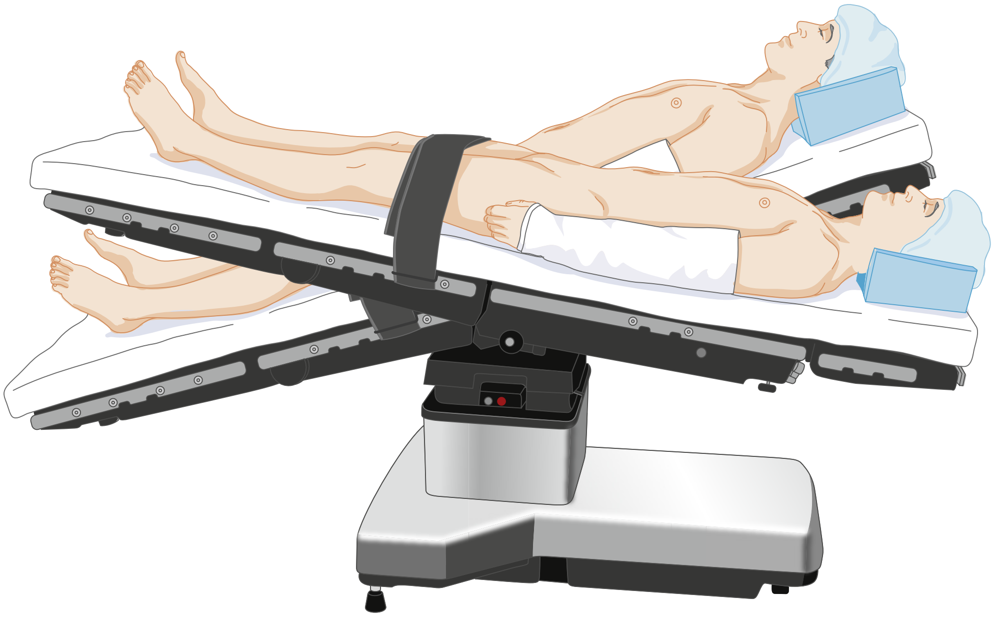

Fig. 34.5 Head-down tilt (Trendelenburg) position and head-up tilt (reverse Trendelenburg) position. Shoulder braces should be avoided to prevent brachial plexus compression injuries.

supine position is not tolerated. Consideration of the impact of positioning on intracranial pressure is important, as it may not only affect intraoperative positioning but also may have consequences on site selection for central line placement. Frequently, femoral vein site selection is preferred in patients with severely elevated intracranial pressure in order to avoid exacerbating intracranial hypertension with patient position changes during line placement.

Prolonged head-down positioning can also lead to swelling of the face, conjunctiva, larynx, and tongue, with an increased potential for postoperative upper airway obstruction. The Trendelenburg position increases intraabdominal pressure and displaces the stomach placing the patient at a higher risk for aspiration. Endotracheal intubation is often preferred in order to prevent aspiration of gastric contents.

Care must be taken to prevent patients in steep head-down positions from slipping cephalad on the surgical instruments.[20,21] Techniques to restrain the patient include antiskid bedding, knee flexion, shoulder braces, beanbag cradling, and padded cross-torso straps.[22] Shoulder braces are specifically not recommended because of the risk of compression injury to the brachial plexus. Beanbag pads become rigid when suction is applied to set the shape, and their use in the Trendelenburg position has been associated with brachial plexus injuries.[23-25] If either shoulder braces or beanbag shoulder immobilization is used to prevent sliding, additional caution is recommended regarding abducting the arm; brachial plexus injuries on the side of the abducted arm have been reported in conjunction with beanbag shoulder immobilization and steep Trendelenburg positioning.[26] These injuries may be due to stretch of the upper and middle trunks of the brachial plexus, as they course around the head of the humerus (Fig. 34.6).

The reverse Trendelenburg position (head-up tilt; see Fig. 34.2) is often used to facilitate upper abdominal surgery by shifting the abdominal contents caudad. This position is increasingly popular because of the growing number of laparoscopic surgeries requiring this position. Again, caution is advised to prevent patients from slipping on the table. As mentioned earlier, any position where the head is above the heart reduces cerebral perfusion pressure and may also cause systemic hypotension. If invasive arterial pressure monitoring is used then the arterial pressure transducer should be zeroed at the level of the Circle of Willis.

Complications of the Supine Position

The base of the surgical table is asymmetric. Classically, the base of the table is directly underneath the patient's torso (see Fig. 34.1). However, sometimes the patient's torso overlies the end of the table without the base underneath it in order to improve surgical access or to facilitate the use of specific equipment such as the C-arm for x-ray. Without the table base under the torso of the patient's body, the table is at risk of tilting or tipping over. This risk is higher with obese patients and when the table is in the Trendelenburg position. The surgical table weight limits are significantly different when the table is reversed and should be strictly observed.

Back pain is common in the supine position because the normal lumbar lordotic curvature is often lost. General anesthesia with muscle relaxation and neuraxial block increases the risk of back pain further due to loss of tone in the paraspinous muscles. Patients with extensive kyphosis, scoliosis, or a history of back pain may require extra padding of the spine or slight flexion at the hip and knee.

Peripheral nerve injury (discussed later in this chapter) is a complex phenomenon with multifactorial causes. The ASA has published several revisions of a practice advisory to help prevent perioperative peripheral neuropathies.[4] Ulnar neuropathy has historically been the most common lesion, although brachial plexus injuries have overtaken ulnar neuropathies in more recent closed claims data associated with general anesthesia.[1,3] Regardless of the position of the upper extremities, maintaining the head in a relatively midline position can help minimize the risk of stretch injury to the brachial plexus.[23] Although no direct evidence suggests

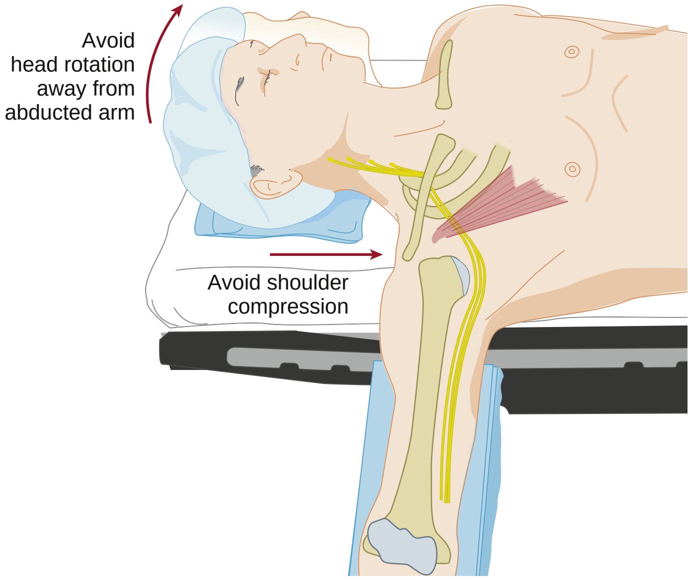

Fig. 34.6 The brachial plexus, shown in *yellow*, is vulnerable to stretch and compression due to its long course. Arm abduction is limited to less than 90 degrees when supine because when the arm is raised the head of the humerus rotates caudad and stretches the plexus. Shoulder braces should be avoided; they may cause direct compression of the plexus medially between the clavicle and first rib or laterally below the head of the humerus. Excessive head rotation should be avoided, especially away from an abducted arm. Abduction of the arm should be avoided when in a steep head-down position if shoulder braces or a beanbag holds the shoulders.

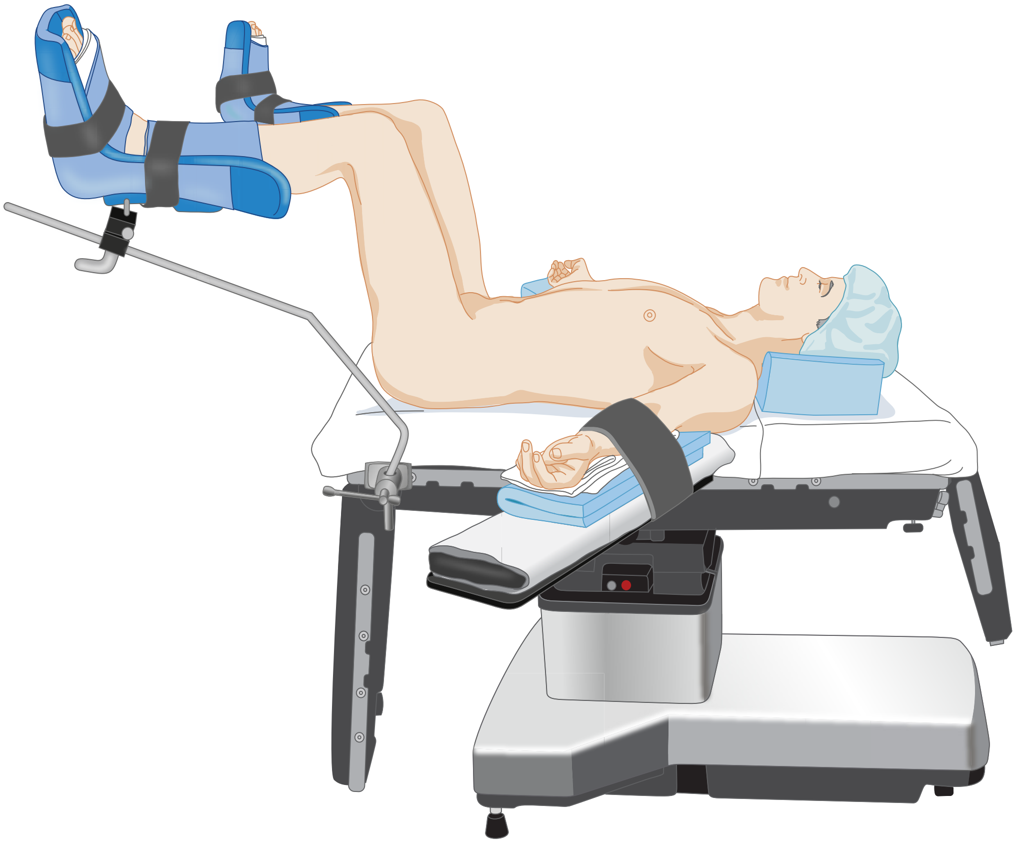

Fig. 34.7 Lithotomy position. Hips are flexed 80 to 100 degrees with the lower leg parallel to the body. Pressure near the fibular head is absent. Arms are on armrests away from the hinge point of the foot section.

that positioning or padding alone can prevent perioperative ulnar neuropathies, the ASA practice advisory recommends limiting arm abduction in the supine patient to less than 90 degrees at the shoulder, with the hand and forearm either supinated or kept in a neutral position.[4]

LITHOTOMY

The classic lithotomy position (Figs. 34.7–34.9) is frequently used during gynecologic, rectal, and urologic surgeries. The patient's hips are flexed 80 to 100 degrees from

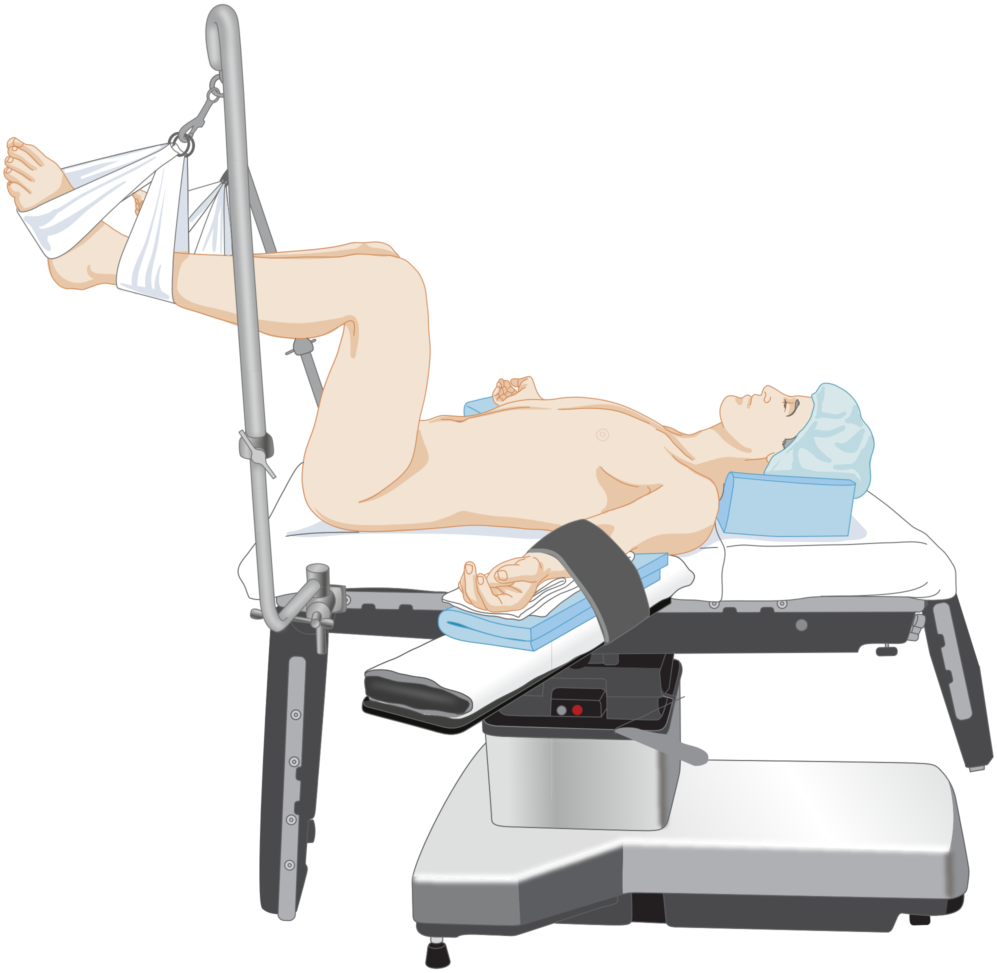

Fig. 34.8 Lithotomy position with "candy cane" stirrup leg holders.

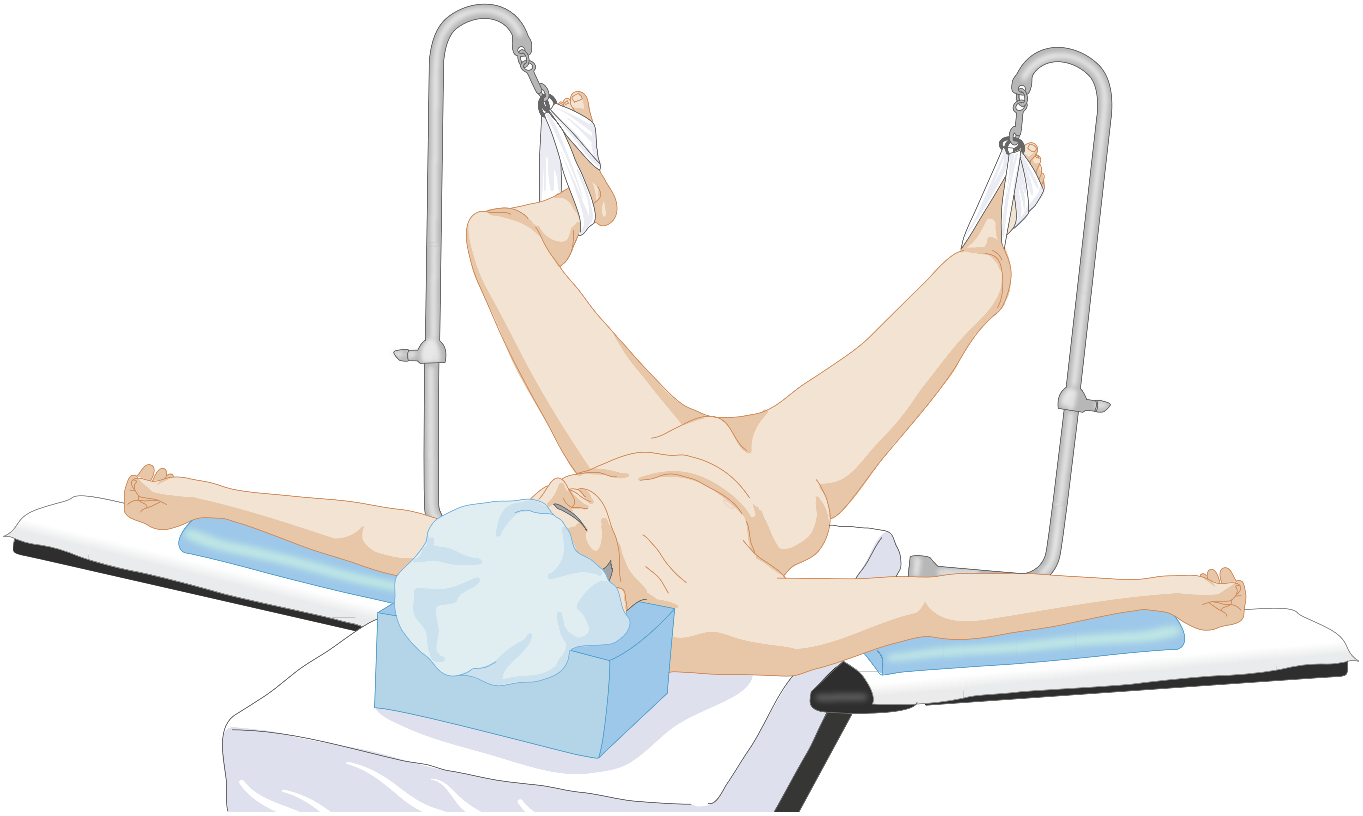

Fig. 34.9 Lithotomy position. The correct position of "candy cane" supports is well away from the lateral fibular head.

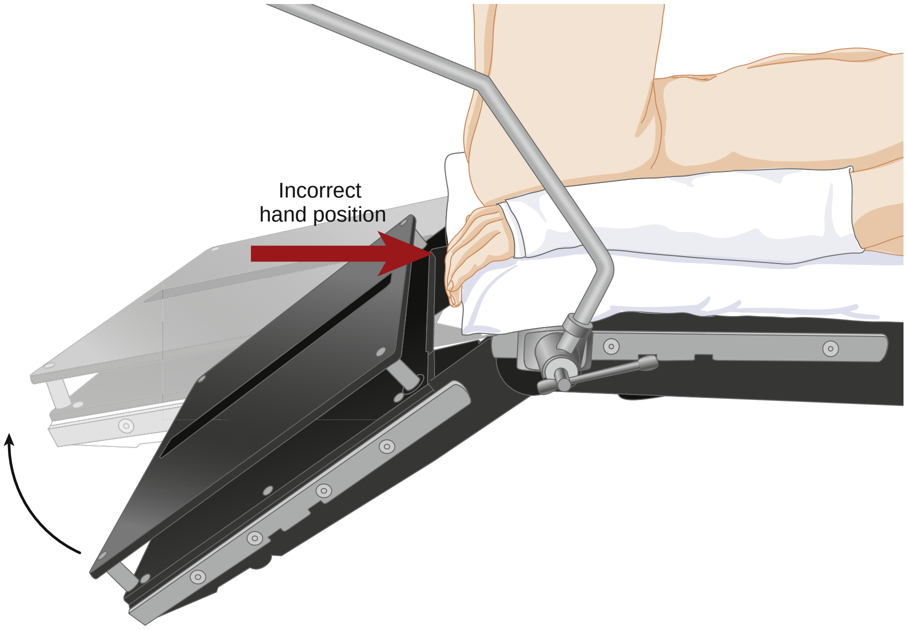

Fig. 34.10 Improper position of arms in lithotomy position. The fingers are at risk for compression when the lower section of the bed is raised.

the trunk, and the legs are abducted 30 to 45 degrees from the midline. The knees are flexed until the lower legs are parallel to the torso. The legs are then placed in supports or stirrups. The foot section of the surgical table is lowered and sometimes removed from the end of the table.

Positioning a patient into and out of lithotomy requires a coordinated team. The legs should be raised together; simultaneously, the knees and hips are flexed. This prevents torsion and injury to the lumbar spine. Padding of the lower extremities is critical, particularly over bony prominences, to prevent compression against the leg supports. The peroneal nerve is particularly prone to injury as it lies between the fibular head and compression from the leg support (see the peripheral nerve injury section of this chapter).

If the arms are tucked or placed alongside the patient, then the patient's hands and fingers are at risk of injury if they lie near the open edge of the lowered section of the table. When the foot of the table is raised at the end of the procedure the fingers near the open edge can get crushed. Strict attention must be paid to the position of the hands to avoid a potentially disastrous crush injury to the fingers (Fig. 34.10). For this reason, the recommended position of the arms is on armrests far from the table hinge point. If the arms must be tucked at the patient's side, then the hands need to be visualized and confirmed to be safe whenever the leg section of the surgical table is manipulated.

The lithotomy position may also cause significant physiologic changes. When the legs are elevated, venous return increases, causing a transient increase in cardiac output and, to a lesser extent, cerebral venous and intracranial pressure in otherwise healthy patients. In addition, the lithotomy position increases intraabdominal pressure and causes the abdominal viscera to displace the diaphragm cephalad, reducing lung compliance and potentially resulting in a decreased tidal volume. In obese patients, or when large abdominal mass is present (e.g., tumor, gravid uterus), abdominal pressure may increase enough to obstruct venous return to the heart. As with the supine position, the curvature of the lumbar spine is lost in lithotomy and can put the patient at risk of back pain.[27]

Lower extremity compartment syndrome is a rare but potentially devastating complication of the lithotomy position. Compartment syndrome is caused by increased tissue pressure within a fascial compartment due to tissue ischemia, edema, and rhabdomyolysis. Inadequate arterial inflow (from lower extremity elevation) and decreased venous outflow (due to direct compression or excessive hip flexion) elevates the risk of compartment syndrome for patients in lithotomy.[28,29] Local arterial pressure decreases 0.78 mm Hg for each centimeter the leg is raised above the right atrium.[30] Reperfusion after ischemic injury further increases edema, exacerbating the problem. In a large retrospective review of 572,498 surgeries, the incidence of compartment syndromes was higher in the lithotomy (1 in 8720) and lateral decubitus (1 in 9711) positions, as compared with the supine (1 in 92,441) position. Long procedure time was the only distinguishing characteristic of the surgeries during which patients developed lower extremity compartment syndromes.[28] A survey of urologists in the United Kingdom suggested that compartment syndrome after surgery in the lithotomy position is underreported and more common than appreciated. Affected patients in this study all had surgical durations greater than 3.5 hours.[31] In a retrospective multicenter review of 185 urologic patients who were placed in high lithotomy position, two patients suffered from compartment syndrome. For both of these patients, operative times exceeded 5 hours.[32] If surgical time extends beyond 2 to 3 hours, periodically lowering the legs is recommended.[32-34] Additional risk includes factors known to compromise tissue oxygenation, such as blood loss, peripheral vascular disease, hypotension, and reduced cardiac output. Elevated body mass index is also a risk factor for compartment syndrome. Intermittent leg compression devices remain controversial.[30,35]

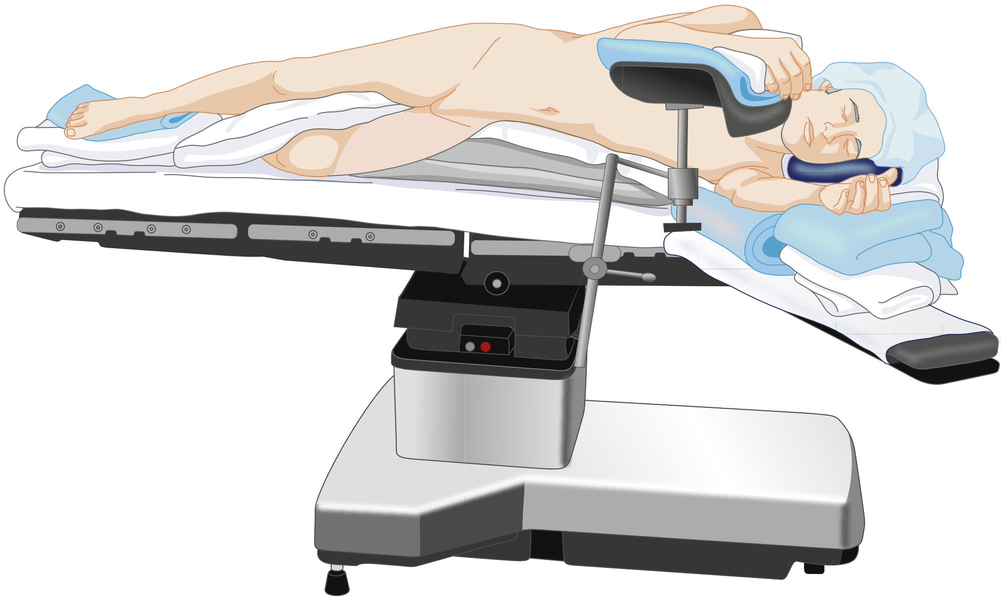

Fig. 34.11 **Lateral decubitus position.** The lower leg is flexed with padding between the legs, and both arms are supported and padded.

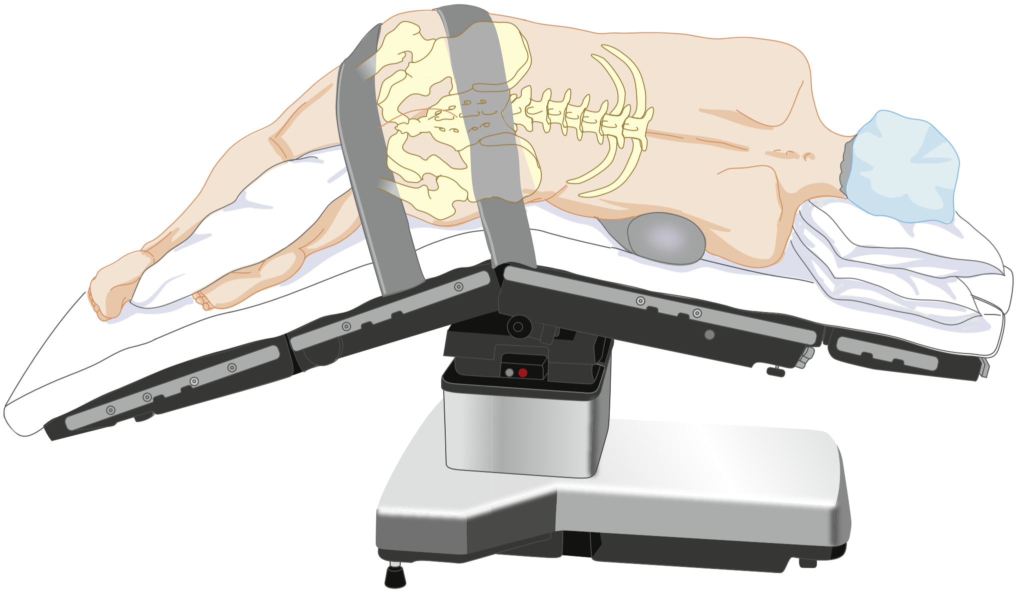

Fig. 34.12 **Flexed lateral decubitus position.** The point of flexion should lie under the iliac crest, rather than under the flank or lower ribs to optimize ventilation of the dependent lung.

LATERAL DECUBITUS

The lateral decubitus position (Fig. 34.11) is most frequently used for surgery involving the thorax, retroperitoneal structures, and hip. Positioning a patient in the lateral decubitus position requires the cooperation of the entire surgical staff. The nonoperative side is dependent and the dependent leg is flexed to minimize stretch of lower extremity nerves. Padding is placed between the knees to minimize excessive pressure on bony prominences. The torso must be balanced and supported both anteriorly and posteriorly. When a kidney rest is used for this purpose, it must be properly placed under the dependent iliac crest to prevent inadvertent compression of the inferior vena cava.

Patients may be laterally flexed while in the lateral position in order to gain better access to the thoracic cavity or retroperitoneum during renal surgeries. The point of flexion and the kidney rest should lie under the iliac crest rather than the flank or ribcage to minimize compression of the dependent lung (Fig. 34.12). The dependent arm should be placed on a padded arm board perpendicular to the torso. The nondependent arm needs to be carefully supported (Fig. 34.13). Neither arm should be abducted more than 90 degrees. For some high thoracotomies, the nondependent arm may need to be elevated above the shoulder plane for exposure; however, vigilance is warranted to prevent neurovascular compromise. The patient’s head must be kept in a neutral position to prevent excessive lateral rotation of the neck and to avoid stretch injuries to the brachial plexus. Often additional head support is required (Fig. 34.14). The dependent ear and eye may be at risk of injury and should be checked regularly.

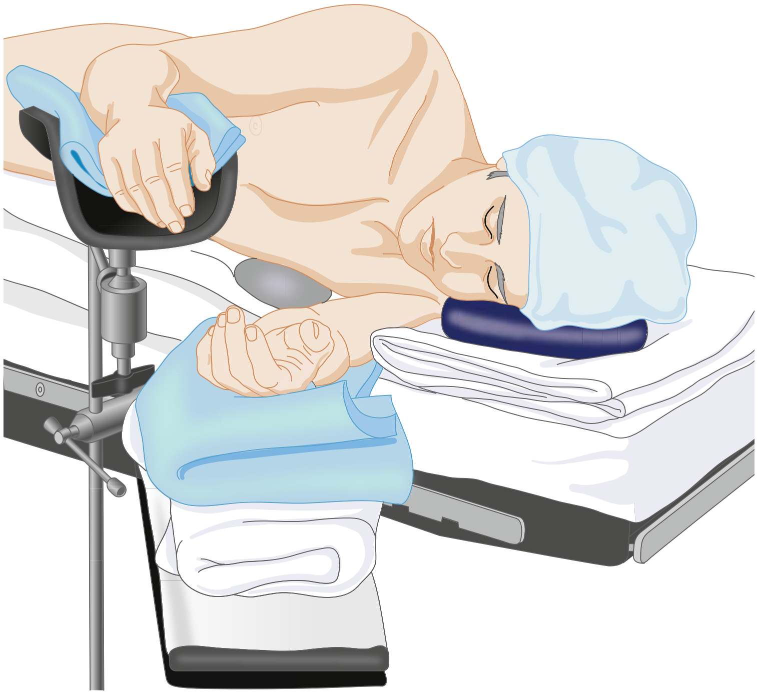

Fig. 34.13 Lateral decubitus position showing placement of arms and head. Additional padding is under the headrest to ensure the alignment of the head with the spine. The headrest is kept away from the dependent eye.

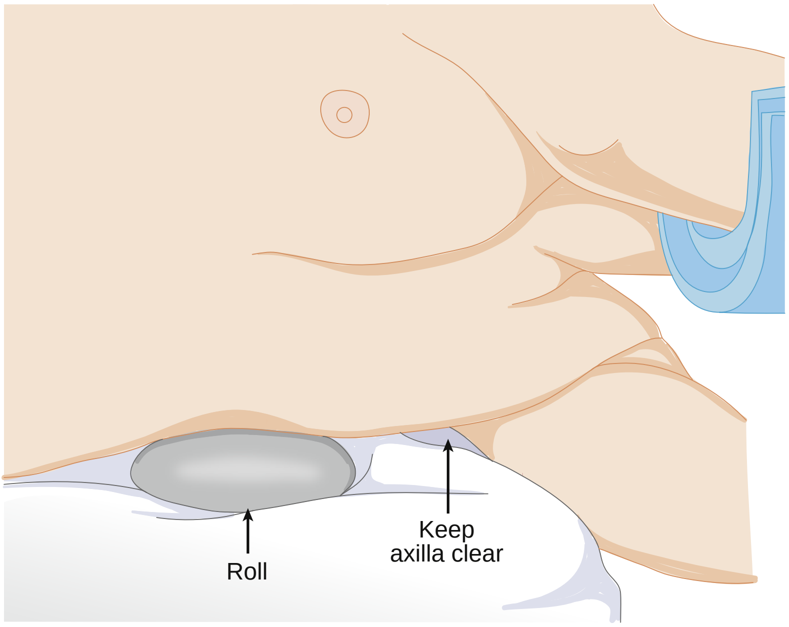

Fig. 34.14 Use of chest roll in the lateral decubitus position. The roll, in this case, is a bag of intravenous fluid and is placed well away from the axilla to prevent compression of the axillary artery and brachial plexus.

The dependent brachial plexus and axillary vascular structures are at particular risk of pressure injury in the lateral decubitus position. In order to avoid compression, an axillary roll is frequently placed between the chest wall and the table just caudal to the dependent axilla (see Fig. 34.13). The purpose of the axillary roll is to protect the dependent shoulder and the axillary contents from the weight of the thorax. The axillary roll should never be placed in the axilla. Sometimes a beanbag is used for positioning without an axillary roll. In this scenario, the axilla should be checked to ensure that it is free from compression. Regardless of the technique, the pulse should be monitored in the dependent arm for early detection of compression to axillary neurovascular structures. Vascular compression and venous outflow obstruction in the dependent arm are risks of the lateral decubitus position. Low pulse oximeter readings can be an early sign of compromised circulation. Similarly, hypotension measured in the dependent arm may be due to axillary arterial compression.

Pulmonary mechanics change in the lateral decubitus position.[36] In a patient who is mechanically ventilated, the

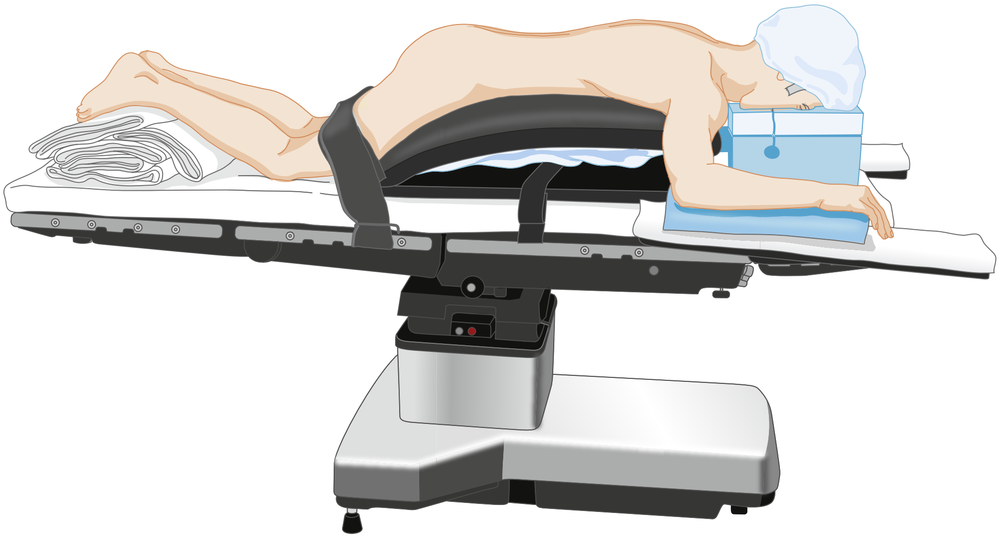

Fig. 34.15 Prone position with Wilson frame. Arms are abducted less than 90 degrees whenever possible, although greater abduction may be better tolerated while prone. Pressure points are padded, and the chest and abdomen are supported away from the bed to minimize abdominal pressure and to preserve pulmonary compliance. Soft head pillow has cutouts for eyes and nose and a slot to permit endotracheal tube exit. Eyes must be checked frequently.

combination of the lateral weight of the mediastinum and the disproportionate cephalad pressure of abdominal contents on the dependent lung favors overventilation of the nondependent lung. At the same time, the effect of gravity causes the pulmonary blood flow to the underventilated, dependent lung to increase. Consequently, ventilation-perfusion matching worsens, potentially affecting gas exchange and ventilation.

The lateral decubitus position is preferred during pulmonary surgery and one-lung ventilation. When the nondependent lung is collapsed, the minute ventilation is allocated to the dependent lung. This, combined with decreased compliance as a result of positioning, may further exacerbate the airway pressure required to achieve adequate ventilation. Head-down tilt in the lateral position worsens pulmonary function yet further, increasing shunt fraction.[37]

PRONE

The prone or ventral decubitus position (Fig. 34.15) is primarily used for surgical access to the posterior fossa of the skull, the posterior spine, the buttocks and perirectal area, and the posterior lower extremities. The patient may receive either monitored anesthesia care or general anesthesia depending on the type of surgery and the patient's body habitus and comorbidities. When general anesthesia is planned, the airway is usually secured via an endotracheal tube while the patient is still supine. Special attention should be paid to securing and taping the endotracheal tube to prevent dislodgement while the patient is prone or during changes in position. Placing an anesthetized patient in the prone position requires the coordination of the entire surgical staff. The anesthesiologist is primarily responsible for coordinating the move while maintaining inline stabilization of the cervical spine and monitoring the endotracheal tube. An exception might be the patient in whom rigid pin fixation is used when the surgeon often holds the pin frame. The endotracheal tube should be disconnected from the circuit during the move from supine to prone in order to prevent dislodgement. Which, and how many, monitors and lines are disconnected during the move is up to the clinical judgement of the anesthesiologist for an individual patient. Lines and monitors connected to the inside arm (the arm moving the least during the move) can often be easily maintained without disconnecting. Ventilation and monitoring should be reestablished as rapidly as possible.

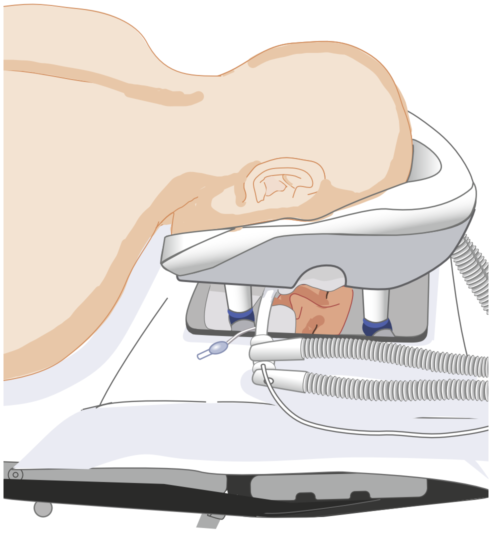

Fig. 34.16 Mirror system for prone position. Bony structures of head and face are supported, and monitoring of the eyes and airway is facilitated with a plastic mirror. Although not illustrated, the eyes should be taped closed.

Prone head position is critical. For patients under sedation, the head may be turned to the side if neck mobility is adequate. During general anesthesia, the head is usually kept neutral using a surgical pillow, horseshoe headrest, or head pins. Weight should be on the bony facial prominences and not soft tissue and especially not on the eyes. The face is not always visible. Mirror systems are available to facilitate intermittent visual confirmation that the eyes are not compressed, although direct visualization or tactile confirmation is prudent (Fig. 34.16). Several commercially available pillows are specially designed for the prone position. Most pillows support the forehead, malar regions, and chin, with a cutout for the eyes, nose, and mouth (see Fig. 34.15). The forehead and malar regions are supported by the horseshoe headrest and allow for reasonable access to the airway (Figs. 34.17 and 34.18). Pin fixation, which is most used in cranial and cervical surgery, is advantageous because there is no direct pressure on the face (Fig. 34.19). Patient movement must be prevented when the head is held in pins; movement in pins can result in scalp lacerations or a cervical spine injury. Both horseshoe and pin headrests attach to the operating room table with adjustable articulating supports. All articulating supports must be fully locked as failure of this bracketing device may lead to complications if the head suddenly drops.

Regardless of the type of head-support technique, proper positioning must be frequently verified during the surgery, checking that there is no pressure on the eyes, that the airway is secure, and that the head weight lies on the bony facial prominences only. The prone position is a risk factor for perioperative visual loss (POVL), which is discussed separately in this chapter. If motor-evoked potentials are used during spine or neurosurgery, then the position of the tongue and placement of bite blocks must be frequently checked; bite injuries can be severe.[38]

A prone patient's legs should be padded and flexed slightly at the knees and hips. The arms may be positioned to the patient's sides or placed outstretched above the head. If the arms are at the patient's sides then they should be tucked in the neutral position. If the arms are outstretched above the head, the arms should be placed on arm boards with slight flexion at the elbows to prevent undue stretch on

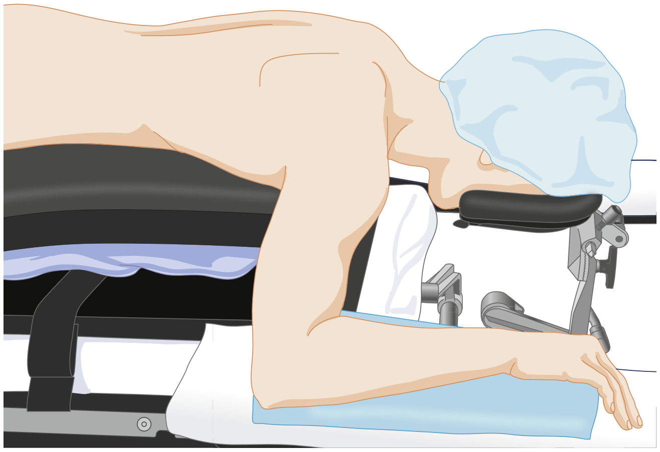

Fig. 34.17 Prone position with horseshoe adapter. Head height is adjusted to position the neck in a natural position without undue extension or flexion.

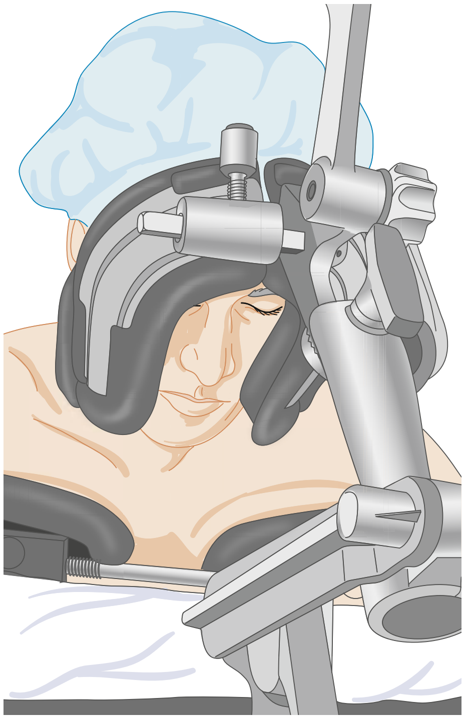

Fig. 34.18 Prone position with horseshoe adapter. The face is seen from below. The horseshoe adapter permits superior access to the airway and visualization of eyes. The width may be adjusted to ensure proper support by facial bones.

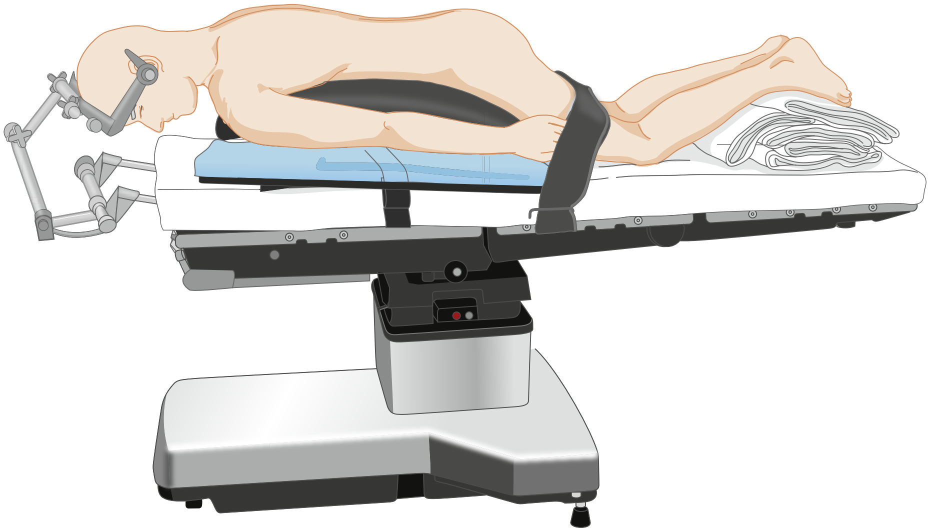

Fig. 34.19 Prone position with Mayfield head pins. Rigid fixation is provided for the cervical spine and posterior intracranial surgeries. The head position may include neck torsion or flexion that affects the depth of the endotracheal tube, and extreme head positions may increase the risk of cervical cord injury.

the peripheral nerves. Extra padding under the elbow may be needed to prevent compression of the ulnar nerve. The arms should not be abducted greater than 90 degrees.

If the legs are in plane with the torso, then hemodynamic reserve is relatively maintained; however, if any significant lowering of the legs or tilting of the entire table occurs, then venous return may increase or decrease accordingly. The prone position does not alter the ability of pulse pressure variation to predict fluid responsiveness. However, the variation has been shown to be augmented at baseline; therefore, fluid responsiveness is observed at a slightly greater level of variation than when supine.[39]

When patients are in the prone position, weight should be distributed to the thoracic cage and bony pelvis, the abdomen should hang freely in order to prevent increases in intraabdominal and intrathoracic pressure. This is accomplished with specific types of prone beds or with gel or foam bolsters. The prone beds and bolsters all place support along each side of the patient from the clavicles to the iliac crests. Placement beyond the iliac crests can cause compression on the femoral vessels and femoral nerve. Some prone beds include the Wilson frame (see Fig. 34.15), Jackson table, Relton frame, and Mouradian/Simmons modification of the Relton frame. Breasts should be placed medially to the prone torso supports (or bolsters), and genitalia should be clear of compression.[40] During posterior spinal surgery, relatively low venous pressure is desirable to minimize bleeding and to facilitate surgical exposure. Elevated abdominal pressure can transmit elevated venous pressures to the abdominal and spine vessels, including the epidural veins, which lack valves. Increased abdominal pressure may also impede venous return through compression of the inferior vena cava, decreasing cardiac output.

Pulmonary function is usually better in the prone position than in the supine position.[41,42] The prone position has been used to improve respiratory function in patients with adult respiratory distress syndrome.[43-45] Under anesthesia, the prone position has advantages over the supine position with regard to lung volumes and oxygenation without adverse effects on lung mechanics,[46,47] including patients who are obese[48] (see also Chapter 58) and pediatric patients (see also Chapter 77).[49] Newer investigations using high-resolution imaging have shown the prone position to provide superior ventilation-perfusion matching in the posterior segments of the lung near the diaphragm when compared with the supine position. The aeration and ventilation of these posterior segments are better, while blood flow is maintained, despite their nondependent position.[8,14]

Other complications of the prone position include airway edema, eye injury, pressure injury, and inadvertent loss of the endotracheal tube, monitoring, and intravenous lines. For long cases, or cases with large intravascular volume shifts, consider checking and documenting an endotracheal cuff leak at the start and end of the case. Lines and tubes need to be placed and should be well secured prior to turning the patient prone.

SITTING

The sitting position offers excellent surgical exposure to the upper posterior cervical spine and posterior fossa. Gravitational venous drainage of blood in the sitting position does decrease blood in the operative field and therefore possibly reduces surgical blood loss.[50] The lawn or beach chair position is a variation of the sitting position and is commonly used for shoulder surgeries (Fig. 34.20). The lawn chair position is really a semi-sitting position, with the head of the patient more reclined than in the traditional sitting position. For the surgeon, its advantages versus the lateral decubitus position are superior access to the shoulder from both the anterior and posterior aspect and the potential for great mobility of the arm at the shoulder joint.[51] Access to the airway is generally excellent in the sitting position, facial swelling is minimized, and pulmonary mechanics are reasonably preserved (Chapter 57).

There are unique risks to the sitting position that require much vigilance. One of the most concerning risks is for venous air embolism (VAE). The veins lie above the level of the heart in this position; therefore, air entrainment through the veins to the heart is a real danger. Furthermore, dural veins are valveless and tented open by the cranium (Fig. 34.21; see also Chapter 57). Other complications from the sitting position include quadriplegia, spinal cord infarction, hemodynamic instability pneumocephalus, macroglossia, and peripheral nerve injuries.[52,53]

Placing an anesthetized patient in the sitting position requires flexion at the torso. Hip flexion should be less than 90 degrees in order to minimize stretch on lower extremity nerves (including the sciatic nerve). Arms are supported so that the shoulders are slightly elevated in order to ensure avoidance of traction on the shoulder muscles and potential stretching of upper extremity neurovascular structures. The knees are also usually slightly flexed for balance and to reduce stretching of the sciatic nerve, and the feet are supported and padded.[54] The patient's head must be specially fixed in the sitting position with either rigid pins or taped into a special headrest.

The head and neck position while in the sitting position has been associated with complications. Surgery in the sitting position was found to be a risk factor for cervical spinal cord injury in a review of the ASA Closed Claims Project database from 1970 to 2007.[55] Although the exact mechanism for cervical spinal cord injury is unknown, cervical hyperextension, cervical hyperflexion, or excessive cervical rotation have been implicated as risk factors. Extreme neck positions can impede both arterial and venous blood flow, causing hypoperfusion or venous congestion of the brain. The patient's cervical range of motion should be examined in the preoperative assessment, and adequate distance should be maintained between the mandible and the sternum when the cervical spine is flexed in order to provide for adequate arterial and venous blood flow.[52,56,57]

VAE is a constant concern in the sitting position due to the position of the surgical field above the level of the heart and the tented open dural venous sinuses. The reported incidence of VAE varies greatly in the literature due to a lack of standardization of measurement and grading scale for VAE. VAE can cause arrhythmias, oxygen (O_2) desaturation, acute pulmonary hypertension, circulatory compromise, and cardiac arrest. If there is a patent foramen ovale (PFO), then the patient is at risk for a paradoxical arterial embolism causing stroke or myocardial infarction. Traditionally, preoperative contrast echocardiography is recommended to evaluate for a PFO. However, failure to detect a PFO on

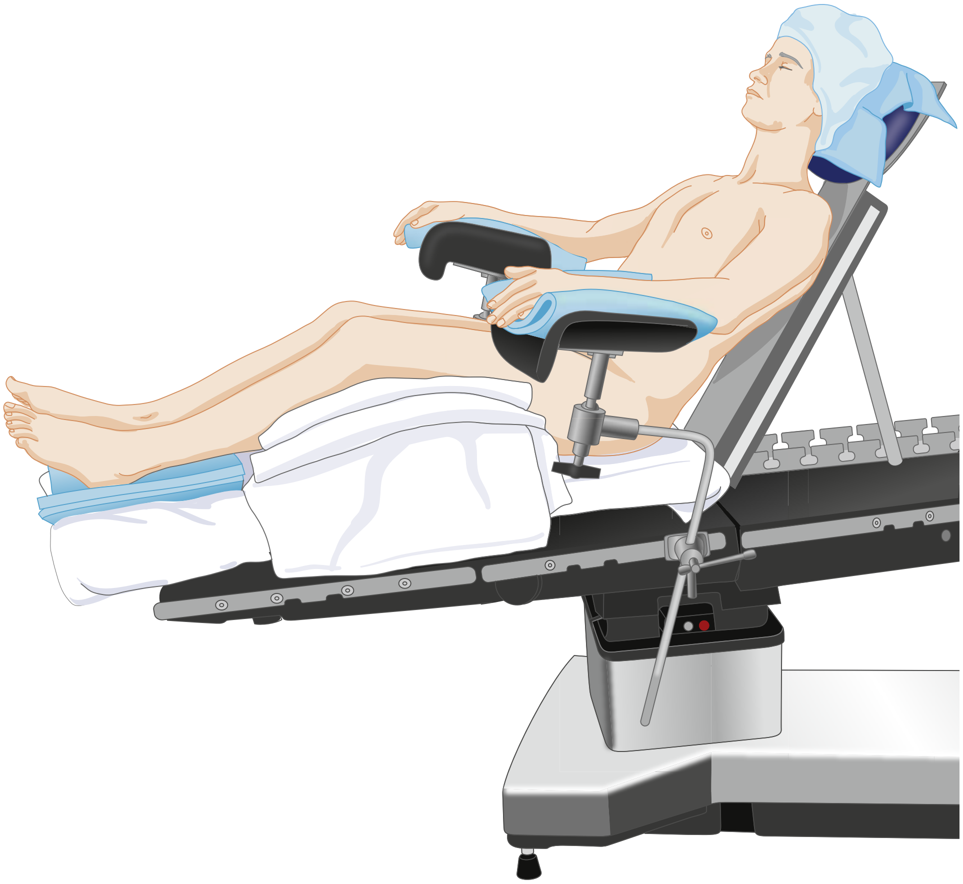

Fig. 34.20 Sitting position adapted for shoulder surgery, often called the lawn or beach chair position. The arms must be supported to prevent stretching of the brachial plexus without pressure on the ulnar area of the elbow. As with all head-up positions, blood pressure should be regulated with the height of the brain in mind.

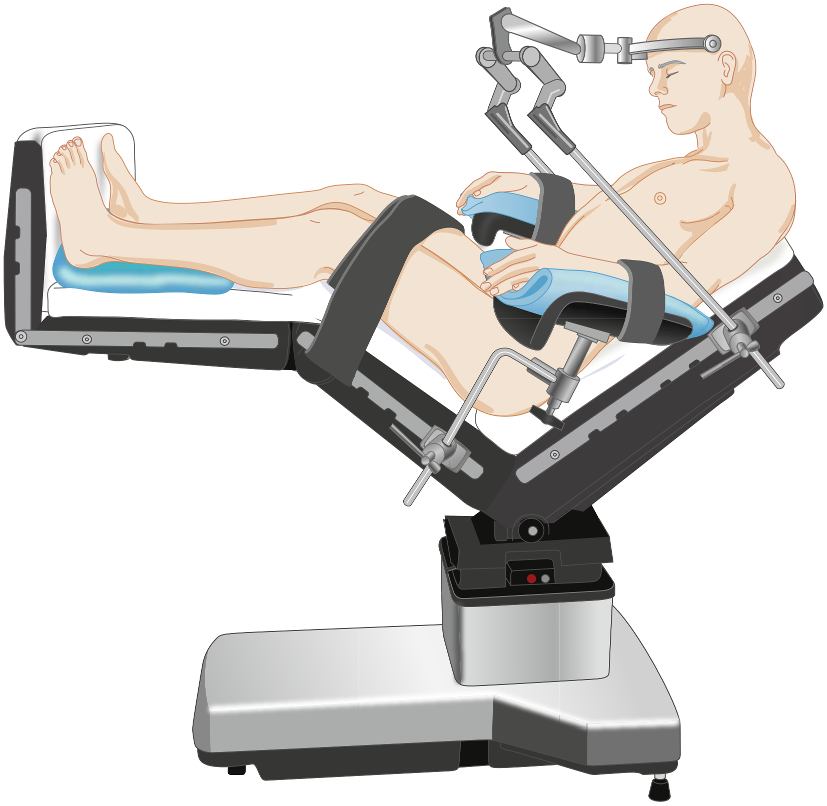

Fig. 34.21 Sitting position with Mayfield head pins. The patient is typically semi-recumbent rather than sitting; the legs are kept as high as possible to promote venous return. Arms must be supported to prevent shoulder traction and stretching of the brachial plexus. In a commonly used variation, the arms are placed on the abdomen and supported. The head support is preferably attached to the back section of the table to allow the back to be adjusted or lowered emergently without first detaching the head holder.

echocardiography does not ensure that the intraatrial septum is intact.[58] The presence of a PFO has generally been considered a contraindication to the sitting position. A recent review suggested that paradoxical VAE is so rare that the presence of a PFO should not necessarily preclude placing the patient in the sitting position. This study found that a VAE was detected in 40% of patients with a known PFO and that no paradoxical embolism was detected.[59] The decision to proceed should be made with patient informed consent and with a discussion between the surgeon and anesthesiologist.

Continuous monitoring for VAE during surgery in the sitting position is essential. There is no standard for type of VAE monitor. Clinical severity of VAE depends on the amount of air and the speed of entrainment. Extrapolation from animal studies suggests that 3 to 5 mL/kg is a lethal amount of air for an adult human, but in reality much less could be required. Transesophageal echocardiography (TEE) is the most sensitive monitor, able to detect as little as 0.02 mL/kg of air. In fact, TEE is so sensitive that some degree of entrained air can be demonstrated in a large majority of patients during neurosurgery in the sitting position.[58,60] Transthoracic Doppler (TTD) is the most sensitive noninvasive monitor with detection rates of approximately 0.05 mL/kg of air. The TTD probe is placed on either the left or right sternal border between the second to fourth intercostal spaces. Transcranial Doppler (TCD) is a monitor of the middle cerebral artery and is nearly as sensitive as TEE. Pulmonary artery catheters, esophageal stethoscopes, and end-tidal carbon dioxide monitors are all much less sensitive monitors. Electrocardiographic and pulse oximeter changes are later findings.[61,62]

Treatment for VAE includes first stopping further air entrainment. The surgeon is asked to stop operating, to flood the field with normal saline, and possibly apply bone wax. The inspired percent of O_2 is changed to 100%. This will aid in treatment during hypoxemia or hypotension and may help reduce the volume of the air embolism via denitrogenation. Hemodynamic compromise is treated with intravenous fluids and vasoactive agents. Consideration is given to placing the patient in left side down and Trendelenburg in order to move an air lock in the right ventricular outflow track (although this can be difficult or impossible in some surgeries).[61] A central venous catheter is often placed preoperatively in order to aspirate entrained air.[58] An exvivo study examining different central venous catheter types and positions found that a multiorifice catheter and single orifice catheter both aspirated 50% to 60% of experimentally introduced air.[63]

Pneumocephalus, quadriplegia, spinal cord infarction, cerebral ischemia, and peripheral nerve injuries are all risks of sitting positions. Pneumocephalus is almost universally found on postoperative imaging from cervical or posterior fossa surgery performed in the sitting position. Tension pneumocephalus, which is accumulation of air in the subdural or ventricular space causing pressure on intracranial structures, is very rare but reported after neurosurgery in the sitting position. Prompt diagnosis and surgical evacuation of air is the treatment. Positioning complications causing quadriplegia or spinal cord infarction are thought to be caused by impaired arterial perfusion with hyperextension, hyperflexion, or excessive rotation of the neck. Theories relating the sitting positions to cerebral ischemia include reduced cerebral perfusion caused by reduced cardiac output, deliberate or permissive hypotension, loss of compensatory mechanisms caused by anesthesia, failure to compensate for the height of the head in the regulation of the blood pressure, dynamic vertebral artery narrowing or occlusion with the rotation of the head, and air emboli. Investigators have demonstrated positional effects on cerebral oxygen saturation,[64] as well as transient reductions in cerebral oxygen saturation associated with hypotensive periods during shoulder surgeries in the sitting position that reversed after use of ephedrine and phenylephrine to restore cerebral perfusion pressure.[64-66] One observational study of 124 patients undergoing shoulder arthroscopy demonstrated cerebral desaturation by oximetry in 80% of those who were in the lawn or beach chair position and none in the lateral decubitus position.[67] Cerebral oxygen saturation monitoring may be helpful; however, no gold standard limits exist, and values may change along with alterations in patient position and carbon dioxide concentration. Therefore, if measured, trends in cerebral oxygen saturation are best interpreted during periods of constant ventilation and patient position.[68,69] Reasonable recommendations for patients undergoing surgery in the sitting position are to monitor blood pressure carefully in reference to the level of the brain, avoid and rapidly treat any hypotension or bradycardia, and position the head carefully to avoid extreme positions that may compromise cerebral vessels.[70]

Hypotension is a known and very common problem for anesthetized patients in the sitting position. Pooling of blood in the lower body places anesthetized patients in the sitting position at particular risk to hypotensive episodes. Studies reveal that mean arterial pressure, systolic blood pressure, and cardiac index all decrease in the sitting position.[52] Therefore, placement of the patient into the sitting position should be incremental in order to adjust for hemodynamic changes. Intravenous fluids and vasopressors should be inline and ready.

ROBOTIC SURGERY

Since its introduction approximately 30 years ago, the use and scope of robotic surgery has expanded greatly. Robotic surgery is now the norm for many types of urologic and gynecologic operations,[71,72] and is extending to other abdominal operations, thoracic surgery, and head and neck operations. Robotic surgery offers technical advantages for surgeons regarding range of motion and accuracy of laparoscopic instrumentation. Once the robot is docked, direct access to the patient is limited. It is therefore imperative that all monitors, lines, and invasive lines are placed prior to docking the robot, and that proper padding and positioning are completed.

Most of the literature about robotic positioning involves urologic and gynecologic operations, which are generally performed with the patient in steep Trendelenburg (30-45 degrees) and lithotomy with arms tucked in neutral position to the sides. The patient must be very well secured in order to avoid slipping in steep Trendelenburg. Non-slip mattresses, chest straps, and shoulder braces may be useful, but shoulder braces are also reported to cause brachial plexus injuries due to stretch between the shoulder and neck. If shoulder braces are employed, monitoring for excessive stretch at the patient's neck is essential. The endotracheal tube should be well secured to avoid migration. Often a tray or table is placed above the patient's face in order to provide protection from laparoscopic equipment.[73-75] It may be prudent to trial the steep Trendelenburg prior to docking the robot to ensure that the patient is properly positioned, does not slip, and can tolerate steep Trendelenburg from a physiologic standpoint.

Physiologic changes during robotic surgery are due to both laparoscopic insufflation as well as positioning. Hemodynamic changes are largely due to laparoscopic insufflation, whereas changes in respiratory mechanics are also affected by positioning. Functional residual capacity is decreased with both laparoscopy and further decreased with the addition of steep Trendelenburg. This is due to a combination of pressure of abdominal contents from laparoscopy and Trendelenburg pushing up on the diaphragm, and can also be worsened by chest fixation that is applied to prevent the patient from slipping off the table. Peak and plateau airway pressures have been shown to rise as much as 50%. Between changes in pulmonary compliance, decreased functional residual capacity, and the need for increased minute ventilation with carbon dioxide insufflation, intraoperative mechanical ventilation can be quite challenging during these cases.[73-76]

The incidence of positioning complications from robotic surgery vary substantially from 0.8% to 6.6%; most studies indicate an incidence of less than 1%.[77-79] One study found longer operative times, higher ASA physical status, and increased intravenous fluid administration to be risk factors for intraoperative positioning complications.[77] A history of prior abdominal surgery was the only associated risk factor found in a study of gynecologic robotic surgeries.[78] Eye injury, peripheral nerve injuries, rhabdomyolysis, and compartment syndrome were the most frequent positioning complications found in patients with robotic assisted radical prostatectomies. Incidence of injury in this study was not different between robotic versus traditional open prostatectomy.[79] In a recent survey of ASA members, 21.7% of responders answered "yes" that they have experienced a "complication related to Trendelenburg positioning (during robotic surgery)." Airway and facial edema, as well as brachial plexus injuries, were the most common recalled complications in this survey.[80] When steep Trendelenburg is used, consideration should be given to documenting the endotracheal tube airway leak at the start and at the end of the surgical procedure prior to extubation.

Peripheral Nerve Injury

Peripheral nerve injury remains a serious perioperative complication and a significant source of professional liability despite its infrequent incidence. The ASA states that "postoperative signs and symptoms related to peripheral nerve injury…may include but are not limited to paresthesias, muscle weakness, tingling, or pain in the extremities."[4] Studies of the ASA Closed Claims Project database (in 1990 and 1999) brought awareness of the incidence of perioperative peripheral nerve injury, which was found to be between 0.03% and 0.11%. However, according to this database, peripheral nerve injuries represented 22% of all claims. In fact, peripheral nerve injury has been second only to death as the leading cause of claims against anesthesiologists.

The overall incidence of peripheral nerve injury claims had increased from 15% in the 1970s.[1,2,81,82] According to a review of 5280 closed claims (from 1990 to 2007), most patients with nerve injuries do recover, however, up to 23% of peripheral nerve injuries remain permanent.[4]

In the closed claims database study, ulnar neuropathy is the most common lesion representing 28% of all peripheral nerve injury claims, followed by the brachial plexus (20%), lumbosacral nerve root (16%), and spinal cord (13%).[2,3] Interestingly, the distribution of nerve injury claims has changed over time. From 1980 through 1984, ulnar neuropathy claims decreased from 37% to 17% in the 1990s, and spinal cord injury claims increased from 8% in 1980 through 1984 to 27% in the 1990s. The incidence of spinal cord injury and lumbosacral nerve root neuropathy increased over this study period and were predominantly associated with regional anesthesia. Epidural hematoma and chemical injuries represented 29% of the known mechanisms of injury among the claims filed.[2,83,84]

In a different retrospective study of 380,680 patients at a single university tertiary care institution, 112 peripheral nerve injuries were observed in the perioperative period, an incidence of 0.3%.[85] Most injuries were sensory (60%) or combined sensory and motor (24%), with only 14% pure motor injuries. This study provides a significantly different numerator and denominator than the ASA Closed Claims Project, and its data contrast with the most recent claims data in which more claims were filed after the administration of regional anesthesia.

Peripheral nerves are made up of bundles of endoneurium wrapped axons bundled into fascicles, which are wrapped in perineurium. Schwann cells provide a myelin sheath to enhance conduction for myelinated nerves. Peripheral nerves are vascular metabolically active structures. The vasa nervorum provides blood flow via a capillary network.[86] Injuries are classified in neurology by the Seddon or Sunderland Classifications. These classifications are based upon neuronal anatomy and can be clinically correlated.[87] There are three main mechanisms for peripheral nerve injury: stretch, compression, and transection. Transection can be partial or complete and can be due to sharp or blunt transection. Compression injuries can be due to compression of vascular structures causing ischemic injury or due to direct nerve or myelin compression.[87] All of these mechanisms can affect sensory and motor nerves.[88]

Perioperative peripheral nerve injury is complex and multifactorial in etiology. Because sensation is blocked by unconsciousness or regional anesthesia, early warning symptoms of pain with normal spontaneous repositioning are absent.[81,89] Patient comorbidities that contribute to peripheral nerve injuries include: hypertension, diabetes, peripheral vascular disease, older age, and heavy alcohol and tobacco use.[4] Extremes of weight, both low body mass index and obesity, are also risk factors. General and epidural anesthesia appeared to be risk factors, compared with monitored anesthesia care, spinal anesthesia, and peripheral nerve blocks. Prolonged surgical times are an additional risk factor.[1,85]

BOX 34.1 Summary of the 2018 American Society of Anesthesiologists Practice Advisory for the Prevention of Perioperative Peripheral Neuropathies

Preoperative Assessment

- Review a patient's preoperative history and perform a physical examination to identify: body habitus, preexisting neurologic symptoms, diabetes mellitus, peripheral vascular disease, alcohol dependency, arthritis, and sex.
- When judged appropriate, ascertain whether patients can comfortably tolerate the anticipated position.

Upper Extremity Positioning

- Positioning Strategies to Reduce Perioperative Brachial Plexus Neuropathy
  - When possible, limit arm abduction in a supine patient to 90 degrees. The prone position may allow patients to comfortably tolerate abduction of their arms to greater than 90 degrees.
- Positioning Strategies to Reduce Perioperative Ulnar Neuropathy
  - Supine Patient with Arm on an Armboard: Position the upper extremity to decrease pressure on the postcondylar groove of the humerus (ulnar groove). Either supination or the neutral forearm positions may be used to facilitate this action.
  - Supine Patient with Arm tucked at Side: Place the forearm in a neutral position.
  - Flexion of the Elbow: When possible, avoid flexion of the elbow to decrease the risk of ulnar neuropathy.
- Positioning Strategies to Reduce Perioperative Radial Neuropathy
  - Avoid prolonged pressure on the radial nerve in the spiral groove of the humerus.
- Positioning Strategies to Reduce Perioperative Median Neuropathy
  - Avoid extension of the elbow beyond the range that is comfortable during the preoperative assessment to prevent stretching of the median nerve.
    - Periodic assessment of upper extremity position during procedures
  - Periodic perioperative assessments may be performed to ensure maintenance of the desired position.

Lower Extremity Positioning

- Positioning Strategies to Reduce Perioperative Sciatic Neuropathy
  - Stretching of the Hamstring Muscle Group: Positions that stretch the hamstring muscle group beyond the range that is comfortable during the preoperative assessment may be avoided to prevent stretching of the sciatic nerve.
  - Limiting Hip Flexion: Since the sciatic nerve or its branches cross both the hip and the knee joints, assess extension and flexion of these joints when determining the degree of hip flexion.
- Positioning Strategies to Reduce Perioperative Femoral Neuropathy
  - When possible, avoid extension or flexion of the hip to decrease the risk of femoral neuropathy.
- Positioning Strategies to Reduce Perioperative Peroneal Neuropathy
  - Avoid prolonged pressure on the peroneal nerve at the fibular head.

Protective Padding

- Padded armboards may be used to decrease the risk of upper extremity neuropathy.
- Chest rolls in the laterally positioned patient may be used to decrease the risk of upper extremity neuropathy.
- Specific padding to prevent pressure of a hard surface against the peroneal nerve at the fibular head may be used to decrease the risk of peroneal neuropathy.
- Avoid the inappropriate use of padding (padding too tight) to decrease the risk of perioperative neuropathy.

Equipment

- When possible, avoid the improper use of automated blood pressure cuffs on the arm to reduce the risk of upper extremity neuropathy.
- When possible, avoid the use of shoulder braces in a steep head-down position to decrease the risk of perioperative neuropathies.

Postoperative Assessment

- Perform a simple postoperative assessment of extremity nerve function for early recognition of peripheral neuropathies.

Documentation

- Document specific perioperative positioning actions that may be useful for continuous improvement processes.

From the Practice Advisory for the prevention of perioperative peripheral neuropathies: an updated report by the American Society of Anesthesiologists Task Force on prevention of perioperative peripheral neuropathies. *Anesthesiology*. 2018;128:11–26.

Ascertaining the presence of preoperative neuropathies and paresthesias is particularly important as injured nerves are more susceptible to injury in a phenomenon described as the double crush syndrome. The theory is that two separate subclinical nerve insults can act synergistically to produce a clinically significant neuropathy.

Usually, the exact mechanism of injury for a particular patient cannot be determined.[2] With the exception of spinal cord injuries, the mechanism of nerve injury remains incompletely explained by scientific studies. Most nerve injuries, particularly those to nerves of the upper extremity such as the ulnar nerve and brachial plexus, occurred in the presence of adequate positioning and padding. Nevertheless, we must prevent nerve injuries to the best of our abilities. The ASA released an updated practice advisory in 2018 to help guide prevention of perioperative nerve injury (Box 34.1).[4] Positions that permit stretching of the nerves and pressure to anatomic locations known to carry nerves prone to injury must be avoided, such as the ulnar cubital tunnel and the peroneal nerve coursing over the fibular head (Table 34.1). Padding and support should distribute weight over as wide an area as possible; however, no padding material has been shown to be superior. Whenever possible, the patient's position should appear natural.

ULNAR NERVE INJURY

The ulnar nerve lies in a superficial position at the elbow. Morbidity associated with ulnar neuropathy can be severe. In a prospective study among 1502 patients undergoing noncardiac surgery, 7 patients developed perioperative ulnar neuropathy, of which 3 patients had residual symptoms after 2 years.[90] In a study on the effect of arm position on the ulnar nerve somatosensory-evoked potentials

TABLE 34.1 Most Common Nerve Injuries in the American Society of Anesthesiologists Closed Claims Database 1990–2010

Nerve Injury	Recommendations for Prevention
Ulnar nerve (14%)	▪ Avoid excessive pressure on the postcondylar groove of the humerus. ▪ Keep the hand and forearm either supinated or in a neutral position.
Brachial plexus (19%)	▪ When utilizing a steep head-down (Trendelenburg) position: ▪ Avoid the use of shoulder braces and beanbags when possible (use nonsliding mattresses). ▪ Avoid abduction of the arm(s) when possible. ▪ Avoid excessive lateral rotation of the head, either in the supine or prone position. ▪ Limit abduction of the arm to <90 degrees in the supine position. ▪ Avoid the placement of high "axillary" roll in the decubitus position—keep the chest roll out of the axilla to avoid neurovascular compression. ▪ Use ultrasound to locate the internal jugular vein for central line placement.
Spinal cord (25%) and lumbosacral nerve root or cord (18%)	▪ Be aware that the fraction of spinal cord injuries is increasing, probably in relation to use of regional anesthesia. ▪ Avoid severe cervical spine flexion or extension when possible. ▪ Follow current guidelines for regional anesthesia in patients on anticoagulant therapy.
Sciatic and peroneal nerves (7%)	▪ Minimize the time in the lithotomy position. ▪ Use two assistants to coordinate simultaneous movement of both legs to and from the lithotomy position. ▪ Avoid excessive flexion of the hips, extension of the knees, or torsion of the lumbar spine. ▪ Avoid excessive pressure on peroneal nerve at the fibular head.

ASA, American Society of Anesthesiologists.
Data from ASA Closed Claims Project 1990 to 2010.
Practice advisory for the prevention of perioperative peripheral neuropathies 2018: An updated report by the American Society of Anesthesiologists Task Force on Prevention of Perioperative Peripheral Neuropathies. *Anesthesiology*. 2018;128:11–26.

(SSEPs) in 15 healthy awake male volunteers, the supinated position was associated with the least pressure on the ulnar nerve, and the neutral position was the next most favorable. When in the neutral position on a surgical armrest, pressure decreased as the arm was abducted between 30 and 90 degrees. Interestingly, not all patients had symptoms of nerve compression when the SSEP was abnormal.[17] Current consensus is that the cause of ulnar nerve palsy is multifactorial and not always preventable.[91,92] In a large retrospective review of perioperative ulnar neuropathy lasting longer than 3 months, the onset of symptoms occurred more than 24 hours postoperatively in 57% of patients; 70% were men and 9% experienced bilateral symptoms. Very thin or obese patients were at increased risk, as were those with prolonged postoperative bed rest. No association with intraoperative patient position or anesthetic technique was confirmed.[93] The ASA Closed Claims Project also demonstrated that perioperative ulnar neuropathy occurred predominately in men, in an older population, and with a delayed onset (median of 3 days).[2] The large predominance of ulnar injury in men may possibly be explained by anatomic differences. Men have a more developed and thickened flexor retinaculum with less protective adipose tissue and a larger tubercle of the coronoid process that can predispose them to nerve compression in the cubital tunnel.[94,95] In the published ASA Closed Claims Project data, only 9% of ulnar injury claims had an explicit mechanism of injury, and in 27% of claims, the padding of the elbows was explicitly documented.[2] Postoperative ulnar nerve palsy can occur without any apparent cause, even when padding and positioning of the patient's arm was carefully managed and documented in the anesthetic record.[18]

BRACHIAL PLEXUS INJURY

The brachial plexus is susceptible to stretching because of its long superficial course from the neck to the arm via the axilla with two points of fixation—the cervical vertebrae and the axillary fascia. The nerves are vulnerable to compression as they pass between the clavicle and the first rib because of the proximity and mobility of both the clavicle and the humerus (see Fig. 34.6). Among patients undergoing noncardiac surgeries, the incidence of brachial plexus injury is reported to be 0.02%.[96] After brachial plexus injury, the patient often complains of sensory deficit in the distribution of the ulnar nerve. This symptom is most commonly associated with intraoperative arm abduction greater than 90 degrees, lateral rotation of the head away from the side of the injury, asymmetric retraction of the sternum for internal mammary artery dissection during cardiac surgery, or direct trauma or compression. To avoid injury, patients should ideally be positioned with the head midline, arms kept at the sides, the elbows mildly flexed, and the forearms supinated, without pressure on the shoulders or the axilla.

Brachial plexus injury is particularly associated with the use of shoulder braces in patients undergoing surgery in the Trendelenburg position. Medial placement of the braces can compress the proximal roots, and lateral placement of the braces can stretch the plexus by displacing the shoulders against the thorax (see Fig. 34.6). The patient with injury often complains of painless motor deficit in the distribution of the radial and median nerves; however, pain may also be present. A report of three cases of upper- and middle-trunk brachial plexopathy after robotic prostatectomy highlights the potential risk of a combination of compression of the shoulder girdle against the thorax in the steep Trendelenburg position with abduction of an arm.[26] Signs of vascular compromise to the upper extremities, such as difficulty obtaining consistent blood pressure or a poor pulse oximetry signal, may be indications of compromise to the neurovascular bundle as reported in a case of bilateral injury related to shoulder braces with abduction of the arms in the Trendelenburg position.[24] Studies of the brachial plexus tension test in human volunteers and nerve strain in cadavers have demonstrated deleterious positional elements including arm abduction, rotation, or flexion of the head away from the affected arm, elbow and wrist extension, and depression of the shoulder girdle.[25] For transaxillary robotic thyroidectomy, a recently developed approach has the arm abducted to 180 degrees. An incidence of brachial plexus injury has been reported to be 0.3%.[97] When an extreme position is used, neurophysiologic monitoring, such as motor-evoked potentials and SSEPs, has been shown to detect an evolving injury and allow for repositioning to prevent permanent damage.[98,99] Nerve function monitoring may therefore become increasingly common with newer surgical techniques that carry increased risk related to patient positioning.

In patients undergoing cardiac surgery requiring median sternotomy, brachial plexus injury has been specifically associated with the C8 to T1 nerve roots. In a prospective study in which the incidence of injury was 4.9%, 73% of the injuries occurred on the same side as the internal jugular vein cannulation; however, this study antedated the widespread use of ultrasound to guide cannulation.[100] Unilateral sternal retraction to harvest the mammary artery is associated with brachial plexus dysfunction, presumably caused by stretching the nerves. SSEP monitoring of the brachial plexus during sternal retraction has been shown to predict injury.[101]

In the 1999 ASA Closed Claims Project report, 10% of brachial plexus injuries were directly attributed to patient positioning. Of those, one half involved the use of shoulder braces in patients in the Trendelenburg position.[2] Consequently, nonsliding mattresses should be used, along with a concerted effort to avoid compression of the shoulders as much as possible.[21,22] Of the 311 brachial plexus injuries in the ASA Closed Claims Project, 59 (19%) occurred after a regional block without general anesthesia, including axillary and interscalene blocks.[2] In those cases, the role of patient positioning cannot be determined.

OTHER UPPER EXTREMITY NERVE INJURY

In a retrospective study of 1000 consecutive spine surgeries that used SSEP monitoring, five arm positions were compared regarding SSEP changes in the upper extremities. A modification of the arm position reversed 92% of upper extremity SSEP changes. The incidence of position-related upper extremity SSEP changes was significantly higher in the prone "superman" (7%) and lateral decubitus (7.5%) positions, compared with the supine arms out, supine arms tucked, and prone arms tucked positions (1.8%-3.2%). Reversible SSEP changes were not associated with postoperative deficits (Chapter 39).[24]

Although quite rare, the radial nerve can be injured from direct pressure as it traverses the spiral groove of the humerus in the lower one third of the arm. The injury often exhibits a wrist drop with an inability to abduct the thumb or extend the metacarpophalangeal joints. An isolated median nerve injury most often occurs during the insertion of an intravenous needle into the antecubital fossa in a patient who has been anesthetized where the nerve is adjacent to the medial cubital and basilic veins. Patients with this injury are unable to oppose the first and fifth digits and have decreased sensation over the palmar surface of the lateral three and a half fingers. Surprisingly, in an evaluation of the ASA Closed Claims Project database from 1970 to 2007, peripheral intravenous and arterial line insertion accounted for 2.1% of all claims filed, particularly among patients who underwent cardiac surgery where the arms were tucked and the lines were not visible for inspection.[102] Nerve injury accounted for 17% of intravenous line complications, second only to skin slough or necrosis (28%) and swelling, inflammation, and infection (17%).

LOWER EXTREMITY NERVE INJURY

Injuries to the sciatic and common peroneal nerves occur most often in the lithotomy position. Because of its fixation between the sciatic notch and the neck of the fibula, the sciatic nerve can be stretched with external rotation of the leg. The sciatic nerve and its branches cross the hip and knee joints and are stretched by hyperflexion of the hips or extension of the knees. The common peroneal nerve, a branch of the sciatic, is most often damaged from the compression between the head of the fibula and an external structure, such as the frame of a leg support. Most often, patients who suffer a peroneal nerve injury will complain of a foot drop and the inability to extend the toes in a dorsal direction or evert the foot. In a prospective study of 991 patients undergoing surgery under general anesthesia in the lithotomy position, the incidence of lower extremity neuropathies was 1.5%, with injuries to the sciatic and peroneal nerves representing 40% of the cases. Interestingly, symptoms were predominantly paresthesia, with onset within 4 hours of surgery and resolution generally within 6 months. No motor deficits were noted, but in a previous retrospective study, the same authors found the incidence of severe motor disability in patients who underwent surgery in the lithotomy position to be 1 in 3608.[103,104]

Injury to the femoral or obturator nerves generally occurs from lower abdominal surgical procedures with excessive retraction. The obturator nerve can also be injured during a difficult forceps delivery or by excessive flexion of the thigh to the groin. A femoral neuropathy will exhibit decreased flexion of the hip, decreased extension of the knee, or a loss of sensation over the superior aspect of the thigh and medial or anteromedial side of the leg. An obturator neuropathy will exhibit an inability to adduct the leg with decreased sensation over the medial side of the thigh.

In a retrospective review of 198,461 patients undergoing surgery in the lithotomy position from 1957 to 1991, injury to the common peroneal nerve was the most common lower extremity motor neuropathy, representing 78% of nerve injuries. A potential cause of the injury was the compression of the nerve between the lateral head of the fibula and the bar holding the legs. When the "candy cane" stirrups are used, special attention must be paid to avoid compression (see Fig. 34.9). The injury was more common with patients who had low body mass index, recent cigarette smoking, or prolonged duration of surgery.[103] Perhaps as a result of an increased awareness of potential injuries, no lower extremity motor neuropathies were reported in a prospective review of 991 patients undergoing surgery in the lithotomy position from 1997 to 1998. Paresthesias in the distribution of the obturator, lateral femoral cutaneous, sciatic, and peroneal nerves were reported in 1.5% of patients, and nearly all recovered. Surgical times longer than 2 hours were significantly associated with this complication.[104]

EVALUATION AND TREATMENT OF PERIOPERATIVE NEUROPATHIES

When a nerve injury becomes apparent postoperatively, it is essential to perform and document a directed physical examination to correlate the extent of sensory or motor deficits with the preoperative examination as well as any intraoperative events. It is prudent to seek neurologic consultation to help define the neurogenic basis, localize the site of the lesion, and determine the severity of injury for guiding prognostication. With proper diagnosis and management, most injuries resolve, but months to years may be required.[88,105,106] In addition, perioperative neuropathies associated with pain must be differentiated from surgically induced neuropathic pain, which is receiving increasing attention by surgeons because it affects an estimated 10% to 40% of surgical patients postoperatively.[107]

If a new sensory or motor deficit is found postoperatively, then electrophysiologic evaluation by a neurologist within the first week may provide useful information concerning the characteristic and temporal pattern of the injury. Another examination after 4 weeks, when enough time has elapsed for the electrophysiologic changes to evolve, will provide more definitive information about the site and severity of the nerve injury. Regardless, electrophysiologic testing must be interpreted within the clinical context. No single test can define the cause of injury. Nerve conduction studies may be useful to evaluate potential peripheral nerve injuries, as they permit the assessment of both motor and sensory nerves. To evaluate motor integrity, the nerve is supramaximally stimulated at two points along its course, and a recording is made of the electrical response of one of the muscles that it innervates. The size of the muscle action potential provides an estimate of the number of motor axons and muscle fibers that are activated by the stimulus. For sensory conduction studies, the nerve fiber is supramaximally stimulated at one point and the sensory nerve action potential is recorded from another point. The latency of the response can be interpreted as a reflection of the number of functioning sensory axons. Nerve conduction studies are useful for several reasons; they may reveal the presence of a subclinical polyneuropathy that made the individual nerves more susceptible to injury and help distinguish between axon loss and demyelination, which has significant implications regarding course and overall prognosis.

For motor neuropathy, an electromyogram can be performed to characterize the injury. An electromyographic examination involves recording the electrical activity of a muscle from a needle electrode inserted within it. If present, abnormalities may point to the affected component in the motor unit, which consists of the anterior horn cell, its axon and neuromuscular junctions, and the muscle fibers that it innervates. Certain findings are suggestive of denervation, including the presence of abnormal spontaneous activity in the resting muscle (fibrillation potentials and positive sharp waves, which results from muscle irritability) and increased insertion activity. Insertion activity increases within a few days of muscle denervation, whereas abnormal spontaneous activity takes 1 to 4 weeks to develop, depending on the distance from the nerve lesion to the muscle. Depending on the pattern of abnormalities, an electromyographic study may distinguish between radiculopathies, plexopathies, and neuropathies.

Most sensory neuropathies are generally transient and require only reassurance to the patient with follow-up visits, whereas most motor neuropathies include demyelination of peripheral fibers of a nerve trunk (neurapraxia) and generally take 4 to 6 weeks for recovery. Injury to the axon within an intact nerve sheath (axonotmesis) or complete nerve disruption (neurotmesis) can cause severe pain and disability. When reversible, recovery often takes 3 to 12 months. Interim physical therapy is recommended to prevent contractures and muscle atrophy.[105,106]

Pressure Injuries

Pressure injuries are a significant source of patient morbidity and healthcare expenditures in the United States and internationally. Approximately 23% of all pressure ulcers occur while patients are in operating rooms.[108] General anesthesia and length of surgical procedure are both risk factors for pressure injury development. The National Pressure Ulcer Advisory Panel recently revised their definitions and classification scales for pressure injuries, formerly referred to as pressure ulcers.[109] Pressure injury is injury to the skin, and/or underlying tissue, due to pressure or shearing forces. Currently, there are no universal guidelines for pressure injury prevention. The Association of Perioperative Registered Nurses and the Joint Commission have statements issued stating that the prevention of pressure injuries is a joint responsibility shared by all members of the healthcare team. Understanding the risks of pressure injury is essential to preventing their occurrence.

Often early signs of pressure injury start with nonblanching skin erythema. The skin is more resistant to pressure injury than muscle and can actually mask a more extensive injury underneath.[110] This is likely due to increased O_2 requirements of muscle. Pressure injuries associated with operations are often not seen at the time of operation but could be diagnosed days after.[111,112] In the supine position, areas most at risk include the sacrum, heels, and occiput. In the prone position, the chest and knees are at highest risk for pressure injury, and in the sitting position, the ischial tuberosities are at greatest risk.[74]

Factors contributing to the development of pressure injuries include pressure over bony prominences, shear force, skin breakdown, compromised blood flow, immobility, and decreased sensation. Infection, inflammation, edema, and steroids are all also contributing factors.[113] Patient comorbidities such as diabetes, peripheral vascular disease, obesity, low body mass index, and poor nutrition are also known risks.[108]

There are case reports, and very few larger studies, assessing specific medical device-related pressure injuries. One retrospective study found that approximately 0.65% of all pressure injuries were due to medical devices. Nasal cannulas, endotracheal tubes, nasogastric tubes, and cervical collars were all associated with pressure injuries.[114]

Hypothermia and hypotension during surgery, such as during cardiopulmonary bypass (CPB) surgery, may increase the incidence of these complications. Pressure alopecia, caused by ischemic hair follicles, is related to prolonged immobilization of the head with its full weight falling on a limited area, usually the occiput. Hard objects should not be placed under the head as they may create focal areas of pressure. Consequently, ample cushioning of the head and, if possible during prolonged surgery, periodic rotation of the head, are prudent to redistribute the weight.

Bite Injuries

Transcranial motor-evoked potentials (Tc-MEPs) are increasingly used for both spine surgical procedures and also neurosurgical procedures. Tc-MEPs involve contraction of the temporalis and masseter muscle, which has been implicated in tongue, lip, and even tooth injuries due to biting motion. Two large retrospective reviews, each with more than 170,000 cases employing Tc-MEPs, found an overall incidence of 0.14% to 0.63%, and the tongue was most frequently injured (~80% of all associated injuries).[38,115] Injury severity ranged from minor bruising to necessity of laceration repair by suture in 15% to 23% of patients.

Macroglossia following surgery in the sitting position has been reported, presumably due to pressure, ischemia, and decreased venous outflow. A recent review of case reports for macroglossia after neurosurgical procedures found macroglossia was associated with prolonged operative times (50% of cases were over 8 hours) and suboccipital and posterior fossa surgeries (40%).[116] Excessive neck flexion can also obstruct the endotracheal tube and place significant pressure on the tongue, leading to edema. Classically, two finger breadth distance between the chin and chest is recommended. Extra caution is advised in cases with neck flexion if TEE is used for air embolism monitoring, because the esophageal probe lies between the flexed spine and the airway and endotracheal tube, adding to the potential for compression of laryngeal structures and the tongue.

At this time there are no specific recommendations for prevention of bite injuries or macroglossia. Double-sided bite blocks may help in surgical procedures using Tc-MEP, although studies of macroglossia document bite blocks in 50% of patients. The most important prevention measures are ensuring proper placement of bite blocks and rechecking placement throughout the case.

Anesthesia Outside the Operating Room

Anesthesia providers are increasingly involved with gastrointestinal endoscopy, cardiac catheterization, interventional radiology, neuroradiology, magnetic resonance imaging, and computed tomography in hospital locations outside the operating room, as well as for office-based procedures (Chapter 73).[117] Anesthesia care may be specifically requested if an individual is not expected to tolerate the position required for the procedure because of comorbidities such as congestive heart failure, pulmonary disease, or morbid obesity. In addition, although positions customarily used for procedures without anesthesia may be generally safe for patients who are awake, they may pose serious risks to those under anesthesia.

Because of the less familiar environment, relative lack of positioning equipment, and a variability in staff and nursing training with regard to patient positioning, planning, and continued vigilance are particularly important in settings outside the operating room. Diagnostic tables may not lend themselves to established intraoperative solutions to patient positioning challenges. The ability to initiate the Trendelenburg position to augment venous return and cardiac output rapidly is often lacking. In such an environment, where practice patterns often evolve in the context of nonanesthetized patients, the anesthesiologist must verify the safety of each patient's position.

Perioperative Visual Loss

POVL is a rare but serious complication. Ischemic optic neuropathy (ION), and retinal arterial occlusion (RAO) are the main causes.[118,119] Other causes include cortical blindness,[120] acute glaucoma,[121] choroidal and vitreous hemorrhage,[122] and gas bubble expansion after retinal surgery.[123] The discussion here is confined to visual loss that follows nonocular surgery because eye damage after ocular surgery is well described in the ophthalmology literature. Most of our attention is focused on retinal artery occlusion and ION.

Retrospective studies, surveys, and case reports provide much of the current knowledge on POVL. Two large studies showed that perioperative ION is rare, occurring in approximately 1 in 60,000 to 125,000 anesthetic procedures in the overall surgical population.[124,125] Spine fusion and cardiac surgery are associated with higher incidence of POVL than other operative procedures. Shen examined the POVL prevalence in the US Nationwide Inpatient Sample, for the eight most commonly performed surgical procedures, excluding obstetric and gynecologic surgery. ION occurred most frequently in spine (3.09/10,000, 0.03%) and cardiac surgery (8.64/10,000, 0.086%).[126] The yearly rates of POVL have been decreasing in the 10-year period from 1996 to 2005, and for spine surgery have continued to decline as well.[126,127] Patil found an overall rate of 0.094% in spine surgery.[128] In previous, smaller case series, Stevens found ION in 4 of 3450 spine surgeries (0.1%).[129] Chang and Miller reviewed 14,102 spine surgery procedures in one hospital, identifying 4 with ION (0.028%).[130] After cardiac surgery, the incidence may be as high as 1.3%,[131] but is between 0.06% to 0.113% in more recent, larger retrospective studies.[132-134]

Myers conducted a retrospective case-control study of 28 patients with visual loss after spine surgery.[135] The ASA Postoperative Visual Loss Registry reported 93 cases of visual loss after spine surgery.[136] Nuttall performed a retrospective case-control study of cardiac surgery patients at the Mayo Clinic.[132] A retrospective, case-controlled study of risk factors in perioperative ION in spine surgery, a collaborative effort of 17 American and Canadian medical centers, has been reported.[137] These studies are described in detail in subsequent sections of this chapter.

RETINAL ISCHEMIA: BRANCH AND CENTRAL RETINAL ARTERY OCCLUSION

Central retinal artery occlusion (CRAO) decreases blood supply to the entire retina, whereas branch retinal artery occlusion

TABLE 34.2 Differential Diagnosis: Eye Examination in Retinal, Optic Nerve, or Visual Cortex Injury*

	AION	PION	Cortical Blindness	CRAO	BRAO
Optic disk	Pale swelling, peripapillary flame-shaped hemorrhages, edema of optic nerve head Late: Optic atrophy	Initially normal Late: Optic atrophy	Normal	Normal Late: Optic atrophy	Normal Late: Optic atrophy
Retina	Normal; may have attenuated arterioles	Normal; may have attenuated arterioles	Normal	Cherry-red macula†; pallor and edema, narrowed retinal arteries	Emboli may be present‡; partial retinal whitening and edema
Light reflex	Absent or RAPD	Absent or RAPD	Normal	Absent or RAPD	Normal or RAPD
Fixation and accommodation	Normal	Normal	Impaired	May be impaired with external compression	May be impaired with external compression

*Typical symptoms and signs are listed. Some patients may have varying findings as a result, among other factors, of timing of examination relative to symptom onset.
†Because of a lack of overlying inner retinal cells in the fovea, the intact choroidal circulation is visible as a cherry-red spot.
‡Cholesterol, platelet-fibrin emboli, calcified atheromatous material.
AION, Anterior ischemic optic neuropathy; *BRAO,* occlusion of a retinal arterial branch; *CRAO,* central retinal arterial occlusion; *PION,* posterior ischemic optic neuropathy; *RAPD,* relative afferent pupillary defect.

(BRAO) is a localized injury; these are generally unilateral. There are four mechanisms: (1) external compression of the eye, (2) decreased arterial supply (embolism to retinal arterial circulation or decreased systemic blood flow), (3) impaired venous drainage, and (4) thrombosis from a coagulation disorder.[138] The most common in the perioperative period is improper positioning with external compression producing sufficiently high IOP to stop blood flow in the central retinal artery. It most often occurs during spine surgery performed with the patient in the prone position. Pressure within the orbit also can be increased after retrobulbar hemorrhage, associated usually with vascular injury from sinus or nasal surgery.[139]

Although rare in most surgical procedures, emboli can directly impair blood flow in the central retinal artery or produce BRAO. Paradoxical embolism from the operative site reaching the arterial circulation through a patent foramen ovale has been reported in perioperative retinal vascular occlusion.[140] Venous drainage can be impaired after radical neck surgery by jugular vein ligation.[141] Retinal microemboli, however, are common during open heart surgery.[142]

Clinical Findings

There is painless visual loss, abnormal pupil reactivity, opacification or whitening of the ischemic retina, and narrowing of retinal arterioles.[143] BRAO is characterized by cholesterol, and calcific or pale platelet fibrin emboli. A cherry-red macula with a white ground-glass appearance of the retina and attenuated arterioles is a “classic” sign.[144] Pallor in the ischemic, overlying retina makes visible the red color of the intact, underlying choroidal circulation, but its absence does not rule out RAO. Differential diagnosis from other causes of visual loss is presented in Table 34.2.

Mechanisms of Retinal Ischemia

The retinal blood supply is derived from the retinal and choroidal vessels.[145] After RAO, some O_2 may still be supplied by diffusion from outer retinal layers via the choroid. In monkeys, eyes with CRAO showed little damage in the macular retina after 97 minutes of ischemia. After 240 minutes, damage was profound and irreversible.[146] But proximal occlusion of the central retinal artery may not necessarily extrapolate to external compression of the eye.[147] Increased IOP from external compression is a more severe insult because of the profound simultaneous decreases in both retinal and choroidal blood flows,[148,149] and the greater susceptibility of the inner retinal cells to damage from pressure.[150] Ischemic tolerance time is probably shorter with external compression.[151,152]

Central Retinal Artery Occlusion

The cause of perioperative CRAO is usually external compression of the eye, although it may also occur in cardiac surgery, suspected from emboli.[153,154] Altered facial anatomy may predispose to damage by pressure from anesthesia masks or headrests. In osteogenesis imperfecta, for example, fibrous coats of the eye are thin and immature because of deficiency of collagen fibers, persistent reticulin fibers, and increased mucopolysaccharide ground substance.[155] Sclerae and corneas are thin and exophthalmos common, rendering the eye more vulnerable to damage from external pressure.[156] The horseshoe headrest leaves limited space for eyes, and the eye may inadvertently contact the headrest. Rectangular and horseshoe headrests were implicated in most reports of external compression.[157,158] Kumar reviewed CRAO cases after spine surgery, noting that signs and symptoms included unilateral vision loss, no light perception, afferent pupil defect, periorbital or eyelid edema, chemosis, proptosis, ptosis, supraorbital paresthesia, hazy or cloudy cornea, corneal abrasion, loss of eye movements, ecchymosis, or other trauma near the eye.[159] Macular or retinal edema, a cherry-red spot, or attenuated retinal vessels were often present. Four patients with external compression had retinal pigmentary alterations, suggesting simultaneous choroidal circulatory ischemia.[160,161] Early orbital computed tomography or magnetic resonance imaging showed proptosis and extraocular muscle swelling.[159] Findings were similar to "Saturday night retinopathy" in intoxicated individuals with ocular compression.[162]

Hollenhorst described unilateral blindness in patients positioned prone for neurosurgery and replicated the findings in monkeys with 60 minutes of elevated IOP together with hypotension (six of the eight human subjects did not have hypotension). In the monkey, histologic findings were retinal edema and dilated vascular channels, followed by retinal structural damage, and axonal loss in the optic nerve 4 months later, due to retrograde axonal degeneration after the death of retinal ganglion cells.[163]

Bui documented that during acute IOP increases in rats, changes in visual function assessed by electroretinography progressed from inner to outer retina, that is, retinal ganglion cells were the most sensitive, abnormal at IOPs 30 to 50 mm Hg; photoreceptors were not affected until IOP was higher.[164] The duration of increased IOP that injures the retina varies, with ischemic times as short as 20 or more than 30 or 45 minutes (Table 34.3).[165,166]

Modern head-positioning devices such as square or circular foam headrests with cutouts for the eyes and a mirror to view the eyes should prevent ocular compression.[167] However, unilateral RAO in a prone-positioned patient whose head was in a square foam headrest with goggles covering the eyes has been reported. There is limited space between the headrest and goggles. The patient exhibited signs of direct compression of the eye by the goggles, which, ironically, were designed as eye protectors.[168]

Orbital compartment syndrome, an acute ophthalmologic injury, requiring prompt decompression to relieve the increased IOP, can occur from perioperative intraorbital hemorrhage, orbital emphysema, or intraorbital bacitracin ointment and has been described during endoscopic sinus surgery.[169] There have also been several case reports[170-172] where its occurrence may have been related to positioning, such as in a patient undergoing spine surgery and positioned prone.

Cardiac Surgery and Retinal Arterial Occlusion

The largest case series of perioperative RAO is in cardiac surgery.[153] This recent study retrospectively examined RAO (CRAO and BRAO) in cardiac surgery using the Nationwide Inpatient Sample. More than 5.8 million cardiac operative procedures were estimated from 1998 to 2013, with 4564 RAO cases, an incidence of 7.8/10,000. Associated with increased RAO were giant cell arteritis, transient cerebral ischemia, carotid artery stenosis, embolic stroke, hypercoagulability, myxoma, diabetes mellitus with ophthalmic complications, and aortic insufficiency. Perioperative factors were bleeding, aortic and mitral valve surgery, and septal surgery. These results indicate that conditions that predispose to embolic phenomena, such as carotid disease, opening of the heart during surgery, and preexisting abnormal retinal vasculature (diabetic retinopathy) are potential predictors for RAO in cardiac surgery. Embolization during CPB remains a cause of retinal vascular occlusion. Better means for detecting and preventing this complication are needed.

Branch Retinal Artery Occlusion

BRAO usually leads to permanent ischemic retinal damage with partial visual field loss. Symptoms may not be immediately apparent if the visual field loss is peripheral or when only a small scotoma is present. BRAO is primarily from emboli and, less often, vasospasm. Most case reports describe embolization from intravascular injections, the surgical field, or CPB in cardiac surgery. Microemboli during CPB have been shown by retinal fluorescein angiography.[173] With a bubble oxygenator, all patients had perfusion defects versus 50% with a membrane oxygenator.[174] In coronary artery bypass graft surgery, multiple calcific emboli in branches of the central retinal artery are not unusual, resulting in visual field deficits of varying size and location.[175] In pigs, mechanisms of air embolism during CPB included nonperfusion, vascular leakage and spasm, red blood cell sludging, and hemorrhage. Priming with perfluorocarbons blocked many of these mechanisms.[176]

BRAO was described in a patient in the prone position for spine surgery. After surgery a patent foramen ovale was

TABLE 34.3 Animal Studies of Retinal Ischemia and Time Required to Produce Injury

Author	Animal	Ischemia Method	Ischemia Time
Hayreh et al. (1980, 2004)[146,147]	Monkey	Central retinal artery ligation	>100-240 min
Ettaiche et al. (2001)[151]	Rat (brown Norway)	Increased intraocular pressure	20 and 40 min
Roth et al., Zhang et al. (1998, 2002)[152,165]	Rat (S-D)	Central retinal artery ligation, increased intraocular pressure	45 and 60 min
Zhu et al. (2002)[166]	Mouse (ND4)	Increased intraocular pressure	30, 45, 60 min

discovered. The patient likely sustained a paradoxical air, fat, or bone marrow embolization from the operative site in the lumbar spine.[140] A large retrospective series on RAO in spine surgery has also recently been published.[154]

Considerations in Head and Neck Surgery

The incidence of orbital complications after endoscopic sinus surgery is estimated at 0.12%.[177] Vascular injury during the procedure can cause orbital compartment syndrome with compression of the arterial and venous circulations and in CRAO and optic nerve injury.[178] Indirect damage to the central retinal artery from intraarterial injections of 1% lidocaine with epinephrine has also been described; the mechanism is thought to be arterial spasm or embolism.[179] Orbital surgery is associated with an estimated 0.84% incidence of vision loss.[180] Risk is higher in patients undergoing facial polytrauma repair, optic canal decompression, or orbital apex surgery from an intracranial approach.[181]

Case reports have described sudden irreversible blindness due to BRAO following injection of various drugs into the head and neck region.[182] Super-selective carmustine injection into the internal carotid artery to treat gliomas, or fat injected into the orbit for cosmetic surgery, also have been complicated by visual loss from RAO. This complication can also occur from a neuroradiologic or angiographic or embolism procedure in the head and neck.[183,184]

Prognosis, Treatment, and Prevention

Perioperative RAO results in permanent loss of vision in most cases. Currently available treatment is unsatisfactory. Ocular massage to more peripheral arterial branches could be instituted to decrease IOP and dislodge emboli, if present.[143] Intravenous acetazolamide may increase retinal blood flow. Five percent carbon dioxide in 95% O_2 can enhance dilation and increase O_2 delivery from retinal and choroidal vessels.[185] Further treatment may include thrombolysis, contraindicated after certain surgical procedures. Fibrinolysis through a catheter in the ophthalmic artery within 6 to 8 hours after spontaneous CRAO was associated with improved visual outcome; pooled analysis of trials showed promising results particularly in incomplete CRAO.[186-189] Localized hypothermia to the eye is a simple technique that has decreased injury in animal studies after ischemia, and probably should be instituted because of its minimal risk.[190-192]

In patients positioned prone for surgery, a foam headrest should be used with the eyes properly placed in the opening; the position of the head and the eyes should be checked intermittently about every 20 minutes by palpation or visualization. A headrest that combines a foam headrest with a mirror immediately below, which enables the eyes to be seen easily during surgery, is useful. The use of goggles to cover the eyes is not advised when the head is positioned prone in a conventional square foam headrest. The horseshoe headrest must be used with great caution, and safer choices are available. For the patient positioned prone for cervical spine surgery, this headrest should not be used because of the likelihood of head movement and compression of the eye. Rather, the most effective method for preventing head movement is to place the head in pins. For most procedures in which the patient is prone, any of the commercially available square foam headrests are recommended, where the head is positioned straight down in the neutral position.

In nasal and sinus surgery and in neuroradiologic procedures, the most important principles are avoidance of inadvertent injections into, or compromise of, the ocular circulation. After endoscopic sinus surgery, patients should be checked for signs of acutely elevated IOP (such as blurred vision, eye pain, and nausea) suggestive of orbital hemorrhage. If present, immediate ophthalmologic consultation should be obtained.

ISCHEMIC OPTIC NEUROPATHY

ION, primarily manifesting spontaneously without warning signs, is the leading cause of sudden visual loss in patients older than 50 years of age, with an estimated annual incidence of nonarteritic ION in the United States of 2.3/100,000.[193] Two types of ION—anterior (AION) and posterior (PION)—have been described and can be arteritic or nonarteritic by mechanism. Arteritic AION, caused by temporal arteritis, is a systemic disease, which generally occurs in patients older than 60 years of age, and has a female preponderance. Spontaneously occurring ION, unrelated to surgical procedures, is usually caused by AION.[194]

Nonarteritic ION is overwhelmingly the type found perioperatively. It has been reported after a wide variety of surgical procedures, most after cardiac surgery,[195] spinal fusion,[137] head and neck surgery,[196,197] orthopedic joint procedures,[198] and surgery on the nose or sinuses.[199] Cases also have been described after vascular surgery, general surgical and urologic procedures (radical prostatectomy), cesarean section and gynecologic surgery, and liposuction.[200] The lack of controlled studies, and poorly defined pathologic and risk factors, still limit understanding of perioperative ION, although a number of recent retrospective case-control studies in spine and in cardiac surgery are yielding increasing knowledge of risk factors.[127,134] An animal model of perioperative ION has recently been described as well.[201]

Mechanisms

Disruption of the blood-brain barrier occurs early in AION. There are sparse studies of PION; thus most of this discussion concerns AION. Fluorescein angiography showed dye leakage in the optic nerve head,[202] correlating with early onset of optic disk edema, even before symptoms. [203] The relationship between disruption of the blood-brain barrier and ischemic injury is not known. Earlier studies showed classic blood-brain barrier properties in the optic nerve head[204]; however, more recent immunohistochemical studies of microvessels in the monkey and human optic nerve head suggest a lack of classic blood-brain barrier characteristics in the prelaminar region,[204] which could explain the early edema.

Guy showed that carotid artery occlusion in rats produced a swollen optic nerve within 24 hours.[205] Positive nitrotyrosine immunostaining in the ischemic optic nerve suggests a possible role for nitric oxide (NO) and O_2 free radicals, expected to increase disruption of the blood-brain barrier. Bernstein produced rodent AION by photothrombotic vessel occlusion, and circulation to the optic nerve was lost within 30 minutes; edema peaked 1 to 2 days later and resolved by 5 days.[206] A pale, shrunken optic nerve resembled the limited pathologic studies of human AION.[207] After 6 days, the optic nerve showed axonal swelling and collapse. By 37 days, the retinal ganglion cells were reduced by approximately 40%. Permanent changes included septal thickening and axonal loss, most evident in the center, also similar to that in the human optic nerve. Presently, the number of cases of ION with documented histopathological study is limited.[208]

Clinical studies of AION with fluorescein angiography showed delayed filling of the prelaminar optic disk in 76% of subjects and was not found in normal eyes. This suggests that delayed filling is the primary process, not disk edema,[194] while Hayreh attributed AION to individual variations in blood supply to the optic nerve.[209] This theory is supported by anatomic studies and the variability of visual loss in AION. But the watershed concept—that impaired perfusion and distribution within a posterior ciliary artery predisposes the optic disk to infarction—is disputed. Arnold and Hepler demonstrated that delayed filling of watershed zones was more common in normal eyes than in patients with AION.[202] Thus reduced perfusion pressure in the region of the paraoptic branches of the short posterior ciliary arteries results in optic disk hypoperfusion, rather than a watershed event.[210] Histopathologic examination in AION showed that the infarction was mainly in the retrolaminar region.[211] This implicates as the source of decreased blood flow the short posterior ciliary arteries as directly supplying the optic disk.

A small optic disk (small cup-to-disk ratio) may increase susceptibility to AION because axons of the optic nerve pass through a narrower opening as they exit the eye. Mechanisms of injury resulting from a crowded disk include mechanical axoplasmic flow obstruction, stiff cribriform plate, and decreased availability of neurotrophic factors to retinal ganglion cells.[212-214]

Blood Supply to the Optic Nerve

ION affects the anterior portion of the optic nerve in AION or beyond the retrolaminar region, and behind the eye in PION. Anatomy of and blood supply to the anterior and posterior optic nerves differ.[209] The anterior portion is proximal to the lamina cribrosa, an elastic, collagenous tissue through which the optic nerve, central retinal artery, and central retinal vein pass as they enter the optic disk. The anterior portion includes the superficial nerve fiber layer and the prelaminar region, a thick tissue that constitutes most of the optic disk volume.[215] The superficial nerve fiber layer, composed of axons extending from the retinal ganglion cells, is anterior to the plane extending across the optic nerve from the peripapillary Bruch membrane. Immediately posterior is the prelaminar region, adjacent to the peripapillary choroid. The laminar region is a transition zone between columns of glial cells and dense connective tissue plates. Astrocytes are predominant in the anterior optic nerve, and oligodendrocytes and microglial cells are more common in the posterior or retrobulbar optic nerve. Neural fibers transit the laminar region through fenestrations. The retrolaminar region is the posterior portion of the optic nerve and consists of meningeal sheaths and myelinated axons. The diameter of the optic nerve is enlarged in this area to approximately 3 mm.

The superficial nerve fiber layer derives its blood supply mainly from arterioles in the retina, although in the temporal regions it may receive blood from the posterior ciliary arteries. The prelaminar region is perfused by centripetal branches of the peripapillary choroid and vessels from the circle of Zinn-Haller (Fig. 34.22), which are not found in every eye.[209] Whether the region has a choroid-derived source of blood is controversial. The laminar region is supplied by centripetal branches from the short posterior ciliary arteries or by the circle of Zinn-Haller, but the short posterior ciliary arteries are the primary inputs. Longitudinal anastomoses of capillaries can be seen in the prelaminar and laminar regions and may provide some circulation, although their functional importance is not clearly known.

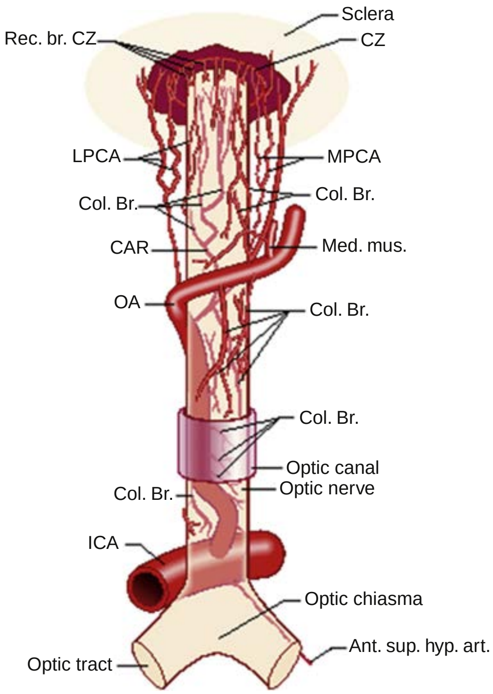

Fig. 34.22 The origin, course, and branches of the ophthalmic artery, including the posterior ciliary arteries, as seen from above. *Ant. sup. hyp. art.*, Anterior superior hypophyseal artery; *CAR*, central retinal artery; *Col. (From Pillanut LE, Harris A, Anderson DR, et al, eds. *Current Concepts on Ocular Blood Flow in Glaucoma*. The Hague, Netherlands: Kugler; 1999.)

The retrolaminar, posterior portion of the optic nerve, which is affected in PION (Fig. 34.23), is perfused by two main vascular supplies. The peripheral centripetal vascular system is the major supply and is found in all optic nerves; it is formed by recurrent branches of the peripapillary choroid and the circle of Zinn-Haller. Pial branches of the central retinal artery and other orbital arteries, the ophthalmic artery, and the posterior ciliary arteries also contribute. Branches of the pial vasculature run in the septa of the nerve. The axial centrifugal vascular system is formed by small branches from the intraneural part of the central retinal artery and is not present in every eye; thus differences in blood supply in the posterior optic nerve may render some individuals more susceptible to PION.[216]

Control of Blood Flow

Studies of autoregulation of blood flow in the optic nerve head have yielded conflicting results because of limited

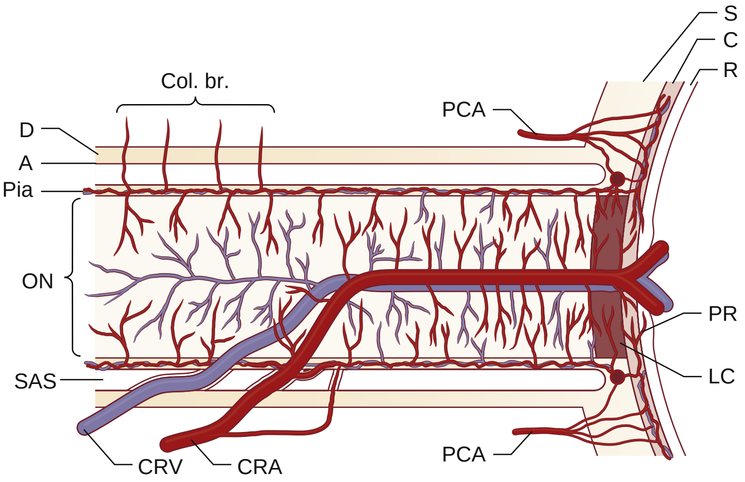

Fig. 34.23 The blood supply to the optic nerve. The anterior portion of the optic nerve is located to the left, whereas the posterior portion (closer to the brain) is on the right. The anterior portion of the nerve derives its blood supply from the posterior ciliary arteries *(PCA)* and the choroid *(C)*, whereas the posterior optic nerve derives its blood supply from penetrating pial arteries (collateral branches *[Col. br.]*) and branches of the central retinal artery *(CRA)*. *A,* Arachnoid; *CRV,* central retinal vein; *D,* dura; *LC,* long ciliary artery; *ON,* optic nerve; *PR,* short posterior ciliary artery; *R,* retina; *S,* sclera; *SAS,* subarachnoid space. measurement techniques. Blood flow in the optic nerve head is autoregulated within a range of perfusion pressures similar to those in the brain of monkeys and sheep. In a small sample of atherosclerotic monkeys, however, autoregulation was defective.[217] This study did not directly measure blood flow; rather, it measured glucose consumption, and the sample size was small. Other evidence of autoregulation is seen in the posterior portion of the optic nerve. In cats, blood flow in the optic nerve measured directly by autoradiography remained constant in the prelaminar, laminar, and postlaminar nerve across a range of systemic mean arterial blood pressure values from 40 to more than 200 mm Hg.[218]

In 13 healthy volunteers, blood flow in the optic nerve head measured by laser Doppler flowmetry was constant between ocular perfusion pressures of 56 to 80 mm Hg.[219]; in another study, flow was preserved at extremely high IOP that resulted in a minimal perfusion pressure of 22 mm Hg.[220] Other investigators found that flow was preserved in the optic nerve head until ocular pressure reached levels of 40 mm Hg. However, 2 of 10 young healthy volunteers in the study failed to demonstrate autoregulation.[221] Using color Doppler imaging in humans, another group showed that flow velocity in the posterior ciliary arteries decreased at extremely high IOP. These findings seem to support the theory that "watershed" areas in the distribution of the posterior ciliary arteries predispose some patients, including otherwise healthy ones with no known vascular disease, to damage to the anterior portion of the optic nerve when perfusion pressure is decreased, either after systemic blood pressure decreases or IOP is elevated. At present, however, no clinical technique can reliably detect such patients.

Histopathologic Findings

There are few reports on the histopathologic examination of the optic nerve in ION. Of three PION cases evaluated after surgical procedures, all showed infarcts in the intraorbital portion of the optic nerve, but results were not consistent. Two patients had lesions in the central axial portion with peripheral axonal sparing; the other had the opposite pattern in one eye and complete axonal loss in the other.[200] Despite a larger autopsy series in AION, the location of the infarct has also not been documented. Tesser and colleagues[207] showed that in a patient with spontaneous AION, axonal loss was in the superior optic nerve, encircling the central retinal artery. The infarct was in the intrascleral portion of the nerve, extending 1.5 mm posteriorly.

Patient Characteristics in Perioperative Ischemic Optic Neuropathy

Most of the cases occurring after spine surgery have been PION.[200] AION occurs more frequently after cardiac surgery. ION's onset is typically within the first 24 to 48 hours after surgery and is frequently noted on awakening, although later onset has been described, particularly in sedated patients.[137] Patients present typically with painless visual loss, afferent pupil defect or nonreactive pupils, complete visual loss, no light perception, or visual field deficits. Color vision is decreased or absent. In AION, altitudinal visual field deficits may be present. Optic disk edema and hemorrhages are seen on symptom onset in AION; in PION, the optic disk appears normal even though the patient reports visual loss. Over a span of weeks to months, optic atrophy develops. The lesion may be unilateral or bilateral, but most post–spine surgery ION cases are bilateral. Orbital magnetic resonance imaging is frequently nondiagnostic, although some have described changes including enlargement of the nerve from edema or perineural enhancement.[222,223] Visual evoked potential and pattern evoked electroretinogram are abnormal.[224]

Retrospective Case Series

Buono and Foroozan reviewed 83 reported cases of PION, some of which were perioperative.[200] Approximately 54% followed spine surgery, 13% radical neck dissection, and 33% other surgery. Mean age was 52 years; patients who had spine surgery were younger (mean age, 44 years) than those in the other groups. Approximately two thirds were men. In 75%, visual loss was apparent within 24 hours. For 54% of affected eyes, initial visual acuity was light perception, with greater than 60% bilateral. In 38%, vision improved, but of 14 patients with no light perception initially, 12 (85%) had no improvement. Mean lowest hemoglobin was 9.5 g/dL (range: 5.8-14.2 g/dL), mean lowest systolic blood pressure was 77 (48-120 mm Hg), mean intraoperative blood loss was 3.7 L (0.8-16 L), and mean operative duration was 8.7 hours (3.5-23 hours). The drawback of this study is the limited amount of information on perioperative ION and its reliance on previously reported cases.

Spine Surgery

Ho reviewed cases of AION and PION after spine surgery. In the 5 AION and 17 PION cases, median ages were 53 and 43 years, respectively.[225] Most followed lumbar spine fusion. Mean operative time for AION was 522 minutes and for PION was 456 minutes. For AION, the range of the lowest mean arterial pressure was 62 to 78 mm Hg; for PION, it was 52 to 85 mm Hg. Mean lowest intraoperative hematocrit was 27% in PION. Mean blood loss was 1.7 and 5 L for AION and PION, respectively. Crystalloid/colloid volumes averaged 6.0/0.8 and 8.0/2.2 L for AION and PION, respectively. Sixty percent with AION and 27% with PION had diabetes mellitus; coronary artery disease was noted in 20% of patients with AION and in none with PION. Prevalence of hypertension was similar (40% or 53%). Symptoms were reported within 24 hours of surgery in 40% of patients with AION; 59% of patients with PION reported symptoms immediately on awakening and 88% within 24 hours. Visual acuity improved somewhat in 60% of AION and 65% of PION cases. This study is limited by its reliance upon literature reports.

In a retrospective case-control study of 28 patients with visual loss after spine surgery, Myers and colleagues found no difference in lowest systolic blood pressure or hematocrit in the affected versus unaffected patients.[135] Approximately 40% of these patients had no risk factors for vascular disease preoperatively; a similar percentage in the two groups had hypertension or were smokers. This study's limitations were that controls were not randomly chosen and matching of controls to cases was not adequately explained.

Spine surgery patients with ION in the ASA Postoperative Visual Loss Registry had an average blood loss of 2.0 L, and the lowest hematocrit was 26%.[136] Decreases in blood pressure varied widely from preoperative baseline: in 33%, the lowest systolic blood pressures were greater than 90 mm Hg; in 20%, the lowest was 80 mm Hg or less. Approximately 57% of patients had systolic or mean arterial blood pressure 20% to 39% below preoperative baseline, and 25% of patients were at 40% to 49% below preoperative baseline. Deliberate hypotension was used in approximately 25% of patients. Nearly all cases involved surgery exceeding 6 hours. In the majority of patients, estimated blood loss was greater than 1 L, the median estimated blood loss was 2 L, and the median lowest hematocrit was 26%. Large-volume fluid resuscitation was typical, with median crystalloid administration of approximately 10 L. Most of the patients underwent thoracic, lumbar, or lumbar-sacral fusion procedures that were often repeat operations that involved multilevel surgery. Surgical positioning devices included the Wilson frame (30%), Jackson spinal table (27%), and soft chest rolls (20%). A foam pad was used for head positioning for 57%; 19% had the head in a Mayfield head holder. PION accounted for the majority of cases, compared with AION. Patients in ASA physical status 1 or 2 accounted for 64% of cases. The mean age was 50 years. Approximately, 41% had hypertension, 16% diabetes mellitus, and 10% coronary artery disease. Limitations of this study are related to data collection and lack of control nonaffected cases for comparison.

TABLE 34.4 Factors Increasing the Odds Ratio of Developing Perioperative ION in Lumbar Spine Fusion Surgery

	Odds Ratio	*P* Value
Male	2.53 (1.35-4.91)	.005
Obesity	2.83 (1.52-5.39)	.001
Wilson frame	4.30 (2.13-8.75)	<.001
Anesthesia duration, per hour	1.39 (1.22-1.58)	<.001
Estimated blood loss, per 1 L	1.34 (1.13-1.61)	.001
Colloid as percent of nonblood replacement, per 5%	0.67 (0.52-0.82)	<.001

This limitation was addressed by a follow-up comparison of the ION spine dataset with randomly selected, matched controls from 17 academic medical centers in North America. Results are summarized in Table 34.4. After multivariable analysis, six factors conferred higher risk for ION in lumbar spine fusion: male gender, obesity, Wilson frame positioning, anesthesia duration, large blood loss, and a relatively low ratio of colloid to crystalloid fluid resuscitation.[137] This study was the first large and well-matched case control study of perioperative ION. The limitations are the relatively limited amount of preoperative data, no distinction between AION and PION, and the possibility that controls did not represent a population-matched sample.

The Nationwide Inpatient Sample is a random sample of discharge data from 20% of US hospitals. Rubin and colleagues analyzed trends in ION incidence in spine fusion from 1998 to 2012 (more than 2.5 million discharges). ION prevalence was 1.02/10,000, with an encouraging, still unexplained, significant decrease over time.[127] Significantly associated with ION were age, blood transfusion, and obesity; female sex was inversely associated. These results are important because they were obtained from a very large, randomly collected sample, and suggested the importance of specific preoperative factors. But there are limitations. The Nationwide Inpatient Sample relies on the accuracy of diagnosis and coding. Verification of medical diagnoses are not possible. Both over- and under-coding are possible. The coding depends on entry of the data by professional coders; however, the accuracy depends upon the diagnoses recorded by physicians and the procedure description provided by the surgeon.[226]

Cardiac Surgery

Shapira and colleagues studied 602 patients undergoing CPB at a single institution under moderate systemic hypothermia (25°C) with pulsatile flow and a membrane oxygenator.[131] Phenylephrine maintained perfusion pressure above 50 mm Hg. Eight patients (1.2%) had AION. There were no differences in preoperative vascular risk factors in those with or without visual loss. CPB time was longer in patients with AION (252 vs. 164 minutes), and minimum hematocrit was lower (18% vs. 21%) compared with unaffected patients. There were no differences in flow indices, perfusion pressures, and carbon dioxide tension. Patients with AION had a greater 24-hour postoperative weight gain (18% vs. 11%) and required more vasoactive drugs to maintain hemodynamics than did patients with unaffected vision. Visual symptoms were usually reported between days 1 and 3 postoperatively, soon after removal of mechanical ventilatory support. This study is limited due to the small sample size and single institution design.

Nuttall and colleagues performed a larger retrospective case-control study of approximately 28,000 patients who had cardiac surgery at the Mayo Clinic from 1976 to 1994, with 17 patients with ION (0.06%).[132] By univariate analysis, significant risk factors included lower minimum postoperative hemoglobin, clinically severe vascular disease, preoperative angiogram within 48 hours of CPB, longer CPB duration, red blood cell transfusions, and the use of non–red blood cell blood components. Patients with ION underwent longer CPB runs; no differences were found in pre-CPB or post-CPB systemic blood pressures. Nine cases of bilateral ION were reported; disk edema was not found in 5 patients (29%), who may have had PION. Small cup-to-disk ratio (<0.3) was identified in 5 patients (29%) with ION. This study was limited by a large number of comparisons, small sample, single institution design, and no distinction between AION and PION. A more recent series by Holy and colleagues showed similar results, but it included other surgical procedures, complicating interpretation of the results with cardiac surgery.[227] Kalyani and colleagues reviewed cases of ION after 9701 cardiac surgeries over 9-year period at a single institution. Specific risk factors could not be determined from the 11 patients (0.11%) with ION.[133]

Rubin examined ION in the largest series of cardiac surgery cases to date, using the Nationwide Inpatient Sample (1998-2012), as described earlier.[134] There were more than 5 million discharges meeting inclusion criteria with 794 (0.014%) ION cases. Average yearly incidence was 1.43 of 10,000 cardiac procedures. Increasing risk were carotid artery stenosis, stroke, diabetic or hypertensive retinopathy, macular degeneration, glaucoma, and cataract. Female sex and uncomplicated diabetes mellitus type 2 decreased risk. This study was large but has the same limitations as other studies using the National Inpatient Sample. Intriguingly, it does suggest that preoperative degenerative eye diseases may predict patients that will develop ION.

Controversies and Anesthesia Management Recommendations

This discussion will primarily concern spinal fusion procedures, where the largest number of cases have been described. For more detail, the reader is referred to the practice advisories of the ASA.[228-230]

Length of Surgery. Both Myers[135] and the Postoperative Visual Loss (POVL) Study Group[137] reported increased risk with long duration of spine fusion surgery. Therefore, staging of spinal fusion procedures, particularly those for anterior and posterior surgery, may be advisable (but see later). A discussion between the surgeon and anesthesia provider should occur in selected cases. Revision spinal fusion procedures are common, and these operations may be longer in duration and involve larger blood loss.[231]

Hypotension. Intraoperative hypotension has been cited as a risk factor by a number of authors of case reports,[232,233] but this risk has not been confirmed by case control studies, with one exception.[135,137,227] Patil and colleagues reported a higher odds ratio for ION in patients who sustained hypotension.[128] However, the diagnostic coding of hypotension in this study from the Nationwide Inpatient Sample is not defined, cannot be confirmed, and the timing (during the perioperative period or not) and the degree of hypotension are not specified.[234]

Hypotension can potentially lead to a decrease in perfusion pressure in the optic nerve and to ischemic injury because of either anatomic variation in the circulation or abnormal autoregulation and an inability to adequately compensate for decreased perfusion pressure. The degree of hypotension that is potentially dangerous is difficult to determine because of the lack of data.[230] Judgment and discussion are thus advisable when surgeons request a decrease in blood pressure to decrease blood loss in spine surgery. In cardiac surgery, special considerations exist regarding the optimal systemic perfusion pressures to be maintained during CPB.[235]

Hemodilution and Blood Loss. Clinical blood transfusion practice in surgical patients, based on ASA practice guidelines,[236] suggests that transfusion is not generally required for hemoglobin values higher than 8.0 g/dL, and thus isovolumic hemodilution is common in patients undergoing spine fusion. The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists reviewed the available evidence with respect to cardiac surgery, and has issued a similar clinical practice guideline.[237] Some authors suggested that allowing hemoglobin to decrease, as is common in anesthesia practice, may increase the risk for ION[238]; however, whether this practice should be changed in surgical procedures such as spine or heart surgery—or in any operative procedure—remains controversial.

In uncontrolled hemorrhage in which blood volume is not maintained, decreased O_2 delivery to the optic nerve could result in either AION or PION.[239] But how low or for how long the hemoglobin concentration must decrease to lead to this complication is not known. However, the presence of recurrent and profound hemorrhage has been described in many reports. The argument that blood loss in the presence of maintained intravascular volume (hemodilution) is harmful seems less scientifically grounded. It has been shown experimentally in miniature pigs that blood flow in the optic nerve head, as measured by laser Doppler imaging, was maintained during isovolumic hemodilution with a 30% decrease in hematocrit. Moreover, O_2 tension at the vitreal surface increased 15%.[240] Also, Lee and colleagues demonstrated that extreme decreases in hematocrit (15%) and mean arterial pressure (50 mm Hg) in adult pigs resulted in significant reductions in blood flow to the optic nerve. But no histologic or optic nerve function was studied, and the pig brain and eye circulation significantly differ from that of humans.[241] Roth and associates showed that hemodilution and extreme head-down tilt in rats resulted in significant changes in visual evoked potentials, electrical activity originating in retinal ganglion cells, and increased glial reactivity in the optic nerve; thus, if extrapolated to humans, caution is in order during extreme hemodilution with the head-down tilt.[201]

Head Positioning. Many reports of ION include patients who were in the prone position, raising the possibility that positioning itself contributes to altered venous hemodynamics within the optic nerve. The patient's head should be level with or above the heart, when possible, and in a neutral position during spine surgery performed with the patient in the prone position. When the patient is positioned for spine surgery in the Wilson frame, the head may be below the level of the back; the head can be elevated using pillows or the bed placed in reverse Trendelenberg.[242] With the Jackson table, the head is maintained at the level with the back.[229]

Several studies found that IOP increased in the prone position and was influenced by the position of the operating room table. However, there has been no correlation between IOP changes and visual outcome or visual function.[242] Cheng and colleagues found that in anesthetized patients, mean (± standard deviations) IOP increased significantly on initial prone positioning relative to supine (27 ± 2 vs. 13 ± 1 mm Hg). After 5 hours in the prone position, IOP remained increased at 40 ± 2 mm Hg. None of the 20 patients in the study experienced visual loss. The largest increases in IOP were evident near the time patients were awakening.[243] Although these data suggest that ocular perfusion pressure may decline even during maintenance of normotension, some experimental design issues must be considered in interpreting these results. The main issue is that the largest increases in IOP were evident near the time of awakening from anesthesia. Accordingly, IOP could have increased because of light anesthesia. Moreover, the study did not include a supine group to control for the effects of fluid administration on IOP. Such control is important because prone positioning itself may not explain the large increases in IOP. These results are valuable as well as of concern, but further studies are needed to fully evaluate their significance.

External pressure on the eye is a potential concern when a patient is positioned prone for surgery. Many cases of ION have occurred when pressure could not have been placed on the eye. Such cases include patients in pin head holders[244] and those in whom the head was turned with the affected eye placed upward.[245] But ION would not occur without retinal damage in a situation in which external compression was applied (see earlier discussion). Although we demonstrated that high IOP decreased retinal and choroidal blood flows in cats,[148] Geijer and Bill specifically measured the impact of graded increases in IOP on blood flow in the retina and optic nerve in monkeys.[246] When IOP was elevated such that perfusion pressure was decreased to levels above 40 cm H_2O, small effects on retinal blood flow and in the prelaminar portion of the optic nerve were noted. When perfusion pressure was less than 40 cm H_2O, retinal and prelaminar flows were proportional to the perfusion pressure. At very high IOP, blood flow stopped in the retina and the prelaminar area, but flow in the retrolaminar region increased. High IOP results in a redistribution of blood flow that favors the retrolaminar portion of the optic nerve. Therefore, an increase in IOP would not produce an isolated ION without also causing retinal damage. Further support is that sustained increases in IOP significantly decreased both retinal and choroidal blood flow, and even small increases in IOP damaged the retinal ganglion cells, which are sensitive to pressure alterations.[247,248]

Fluid Administration. The theory that massive intravascular fluid resuscitation could be a pathogenic factor in perioperative ION remains speculative, but it does have some merit. Conceivably, fluid administration could result in increased IOP, accumulation of fluid in the optic nerve, or both. Because the central retinal vein exits out of the optic nerve, an internal compartment syndrome may occur in the optic nerve. Alternatively, fluid accumulation in the vicinity of the lamina cribrosa may compress axons as they transit this region. In the report by Cullinane and colleagues,[249] trauma patients who were acidotic received massive blood replacement and most had abdominal compartment syndrome. Analysis of these patients is complicated because of the presence of numerous systemic alterations. Sullivan and colleagues described a retrospective series of 13 burn patients with 25% or greater body surface area burns and massive fluid resuscitation. IOP was elevated more than 30 mm Hg in four patients at 48 hours after admission, all of whom received more than 27 L of intravenous fluid. Eye findings and vision diagnoses were not described.[250] Large-volume fluid replacement is generally seen in spinal fusion surgery.[251] Patients in the ASA Postoperative Visual Loss Registry received on average 9.7 L of crystalloid intraoperatively,[137] and increased postoperative weight gain was identified in a case-control study of visual loss after heart surgery,[131] suggesting, although not proving, that fluid replacement may play a role. The finding of the POVL Study Group was that the odds ratio for developing ION was increased as the percent colloid of nonblood replacement decreased.[137] It is possible that the use of colloids may decrease edema in the optic nerve during surgery, particularly when the patient is placed prone for surgery. However, at present, such edema has not yet been demonstrated. In healthy volunteer subjects, placement in the prone position led to an increase in diameter of the optic nerve.[242] This could be due to venous hypertension. New magnetic resonance imaging methods may enable the study of edema and venous hemodynamics in the optic nerve in the near future. Animal models also may provide a means to study these perioperative factors. No study has shown any relationship among periorbital edema, IOP, and ION. Fluid administration could be a pathogenic factor in ION, especially in patients positioned prone or undergoing cardiac surgery, but the mechanisms involved, in addition to the amounts and nature of fluid required, remain undefined.

Anatomic Variation. Anatomic variation in the circulation of the optic nerve may potentially predispose patients to the development of ION. The location of potential watershed zones in the anterior and posterior circulation and the presence of disturbed autoregulation, even in normal patients,[108] are of concern but at present cannot be predicted clinically. Few human studies have been conducted on the relationship between perfusion pressure and changes in blood flow in the optic nerve. Human studies generally show preserved blood flow at clinically used or even lower ranges of perfusion pressure, but these studies have focused primarily on the anterior portion of the optic nerve.[219] In the studies that used laser Doppler flowmetry, depth of penetration of the measuring device is critical. Measurements might have been closer to the retinal blood vessels than the optic nerve head, and these do not measure optic nerve circulation. It is not currently feasible to measure blood flow in the human retrolaminar optic nerve. In animal studies, blood flow is preserved in various layers of the optic nerve, including the retrolaminar area, at a mean arterial blood pressure as low as 40 mm Hg.[218]

Vasoconstrictors. Hayreh and colleagues theorized that AION is related to excessive secretion of vasoconstrictors, which in turn could lower optic nerve perfusion to dangerously low levels.[252] However, the theory was based on the development of AION in patients who sustained massive hemorrhage. Vasopressors are used to maintain blood pressure in circumstances, such as after cardiac surgery and in cases in which vasomotor tone is decreased. Shapira and colleagues showed an association between prolonged use of epinephrine or long bypass time and ION in patients undergoing open heart surgery.[131] Lee and Lam reported a case of ION in a patient after lumbar spine fusion during which phenylephrine infusion was used to maintain blood pressure.[253] They later presented a series of four case reports of ION in critically ill patients with significant systemic illness who required prolonged use of vasopressors and inotropic agents to maintain blood pressure and cardiac output. However, α-adrenergic receptors are not located in the optic nerve and the blood-brain barrier prevents entry of systemically administered agents, except possibly in the prelaminar zone of the nerve. Therefore, the role of vasopressor use in ION remains unclear, and no clear guidance with respect to risk for ION can be provided at this time.

Informed Consent. A single institution survey reported that patients prefer to be informed of the risk of visual loss in spine surgery.[254] It seems advisable to have the discussion with patients that are at higher risk of developing ION. Often it is difficult to do when, as is common, the patient is first seen soon before surgery. It may be preferable for anesthesiologists and surgeons to develop a means to inform patients earlier of the risk of ION.

Staging and Minimally Invasive Spine Fusion. Increasingly, neurosurgeons have been using minimally invasive surgical techniques for lumbar spine surgery and fusion.[255] These methods reduce the amount of blood loss and fluid requirements, but cases of ION have arisen under these circumstances as well.[256] Another strategy not under the direct control of the anesthesia provider is to consider staging of complex spine procedures. However, in some instances the anesthesiologist may be able to persuade a surgeon to follow a less ambitious surgical plan. This decision requires an assessment of the associated increased risks for multiple surgeries (infection, spinal instability) but may significantly shorten the duration of each procedure. However, perioperative complications such as infection and deep vein thrombosis may be increased.[257-261] Another strategy is to advocate for patients by regular preoperative conferencing with surgeons. Anticipating high blood loss and other risks may enhance perioperative planning and care in spine surgery patients.

Prognosis, Treatment, and Prevention

No effective treatment exists for ION. A few cases of treating perioperative ION have been reported. Acetazolamide decreases IOP and may improve flow to the optic nerve head and retina. Diuretics such as mannitol or furosemide reduce edema.[262] In the acute phase, corticosteroids may reduce axonal swelling, but in the postoperative period they may increase wound infection. Because steroids are of unproven benefit, their use must be carefully weighed.[263] Increasing ocular perfusion pressure or hemoglobin concentration may be appropriate when ION is found in conjunction with significant decreases in blood pressure and hemoglobin concentration. Maintaining the patient in a head-up position if increased ocular venous pressure is suspected may be advantageous, but its use must be balanced against decreased arterial supply with the head-up position. Clearly, if a patient has visual loss from ocular compartment syndrome, immediate decompression (lateral canthotomy) is indicated.

In their review of perioperative PION reports in the literature, Buono and Foroozan summarized the lack of proof that treatment altered the course of PION. In a few anecdotal case reports, increasing blood pressure or hemoglobin, or applying hyperbaric O_2, improved visual outcome.[200] The use of neuroprotective agents or drugs that lower IOP, valuable in theory, has never been shown to result in improvement.[248] Stevens and colleagues, who compiled a report of ION in patients after spine surgery, had apparent improvement of vision in two patients when anemia and hypotension were corrected.[129] One patient demonstrated partial improvement that subsequently regressed, and one patient showed more clear signs of improvement. However, as Buono and Foroozan mentioned, it is difficult to ascertain if improvement came from treatment, because some patients recover vision spontaneously after PION.[200]

American Society of Anesthesiologists Advisories (Updated With 2019 Advisory)

The 2006 ASA Task Force on Perioperative Blindness concluded that high-risk patients who have surgery that is prolonged in duration and/or have large blood loss have an increased risk of POVL.[228] Yet POVL was not related to blood loss per se, hemoglobin levels, or the use of crystalloids. In 2012, another ASA Task Force published an update regarding POVL primarily associated with spine surgery.[229] While major changes were not made, analysis of the literature was updated and the recommendations were more detailed. For example, the 2006 Summary had 7 bullet points. In contrast, the 2012 Summary of Advisory Statements has 22 bullet points subdivided into Preoperative, Intraoperative, Staging of Surgical Procedures, and Postoperative Management (Box 34.2). The 2012 ASA Task Force on POVL reviewed the additional literature and concluded that newer findings and the literature do not justify major

BOX 34.2 American Society of Anesthesiologists 2012 Task Force Summary of Advisory Statements

I. Preoperative Considerations

- At this time, there were no identifiable preoperative patient characteristics that predispose patients to perioperative posterior ischemic optic neuropathy (ION).
- There is no evidence that an ophthalmic or neuro-ophthalmic evaluation would be useful in identifying patients at risk for perioperative visual loss.
- The risk of perioperative ION may be increased in patients who undergo prolonged procedures, have substantial blood loss, or both.
- Prolonged procedures, substantial blood loss, or both are associated with a small, unpredictable risk of perioperative visual loss.
- Because the frequency of visual loss after spine surgery of short duration is infrequent, the decision to inform patients who are *not* anticipated to be "high risk" for visual loss should be determined on a case-by-case basis.

Intraoperative Management

Blood Pressure Management

- Arterial blood pressure should be monitored continually in high-risk patients.
- The use of deliberate hypotensive techniques during spine surgery can be associated with the development of perioperative visual loss. Therefore the use of deliberate hypotension for these patients should be determined on a case-by-case basis.
- Central venous pressure monitoring should be considered in high-risk patients. Colloids should be used along with crystalloids to maintain intravascular volume in patients who have substantial blood loss.

Management of Anemia

- Hemoglobin or hematocrit values should be monitored periodically during surgery in high-risk patients who experience substantial blood loss. A transfusion threshold that would eliminate the risk of perioperative visual loss related to anemia cannot be established at this time.

Use of Vasopressors

- There is insufficient evidence to provide guidance for the use of α-adrenergic agonists in high-risk patients during spine surgery.

Patient Positioning

- The Task Force believes that there is no pathophysiologic mechanism by which facial edema can cause perioperative ION. There is no evidence that ocular compression causes isolated perioperative anterior ION or posterior ION. However, direct pressure on the eye should be avoided to prevent central retinal artery occlusion (CRAO).
- The high-risk patient should be positioned so that the head is level with or higher than the heart when possible.

Staging of Surgical Procedures

- Although the use of staged spine surgery procedures in high-risk patients may entail additional costs and patient risks (e.g., infection, thromboembolism, or neurologic injury), it also may decrease these risks and the risk of perioperative visual loss in some patients.

Postoperative Management

- The consensus of the Task Force is that a high-risk patient's vision should be assessed when the patient becomes alert.
- If there is concern regarding potential visual loss, an urgent ophthalmologic consultation should be obtained to determine its cause.
- There is no role for antiplatelet drugs, steroids, or intraocular pressure-decreasing drugs in the treatment of perioperative ION.

From Practice advisory for perioperative visual loss associated with spine surgery: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Visual Loss. *Anesthesiology*. 2012; 116: 274–285.

changes in the 2006 recommendations. A further update was published in 2019.[230]

VISUAL LOSS AFTER VITRECTOMY AND VITREAL GAS BUBBLE TAMPONADE

Patients who have undergone vitrectomy with perfluorocarbon gas tamponade (C_3F_8) are at risk for gas bubble expansion and loss of vision from acutely increased IOP. Patients anesthetized for a subsequent surgical procedure with gas mixtures containing nitrous oxide (N_2O) after vitrectomy sustained retinal vascular occlusion from acute gas bubble expansion. N_2O anesthesia affects the size of the intraocular gas bubble. Wolf and colleagues demonstrated that N_2O and O_2 resulted in a more than threefold increase in SF_6 gas bubble volume, in contrast to a 50% increase with air ventilation and 35% increase with O_2 ventilation alone.[264] Perfluorocarbon gas remains in the eye for at least 28 days. Visual loss has been reported with N_2O anesthesia administered as long as 41 days after vitrectomy and gas bubble tamponade. Therefore, patients should wear a warning tag to alert the anesthesiologist to the presence of the gas bubble in the vitreous, and N_2O should not be used in patients who have had recent vitrectomy and gas bubble tamponade.[265,266]

Conclusion

The positioning of patients under anesthesia care is a major responsibility requiring great attention to detail and constant vigilance. Positioning for optimal surgical exposure but the potential for lasting harm to patients from improper positioning must guide our actions. Each position has significant physiologic effects on ventilation and circulation. In addition, despite increased awareness, position-related complications, including peripheral nerve injuries, continue to remain a significant source of patient morbidity. As surgical techniques evolve, extreme positions sometimes permit advantages, such as smaller incisions and more effective displacement of internal organs to facilitate surgical exposure. Unfortunately, associated risks may increase with positions that would not be tolerated when patients are awake. Anesthesiologists and surgeons must work together with all operating room staff when each patient is positioned to promote comfort and safety in addition to securing the desired surgical exposure. Ideally, the final position should appear natural; that is, a position that the patient would comfortably tolerate if awake and unsedated for the anticipated duration of the procedure.

Disclosure

Dr. Roth's research on vision loss is supported by National Institutes of Health Grants EY10343, EY027447, the Michael Reese Foundation Pioneers Award, and by the North American Neuro-ophthalmological Society. Dr. Roth discloses that he has provided expert witness evaluation and testimony in cases of perioperative visual loss on behalf of patients, hospitals, and healthcare providers.

Acknowledgment

This chapter is a consolidation of two chapters in the 8th edition, Chapter 41, "Patient Positioning and Associated Risks," and Chapter 100, "Postoperative Visual Loss." The editors and publisher would like to thank authors Lydia Cassorla and Jae-Woo Lee, as well as returning author Dr. Steven Roth for their contributions to the prior edition of this work. It has served as the foundation for the current chapter.

Neuromuscular Disorders Including Malignant Hyperthermia and Other Genetic Disorders

JIE ZHOU, ALA NOZARI, BRIAN BATEMAN, PAUL DENNEY ALLEN, and
ISAAC NESS PESSAH

KEY POINTS

- Malignant hyperthermia (MH) is a pharmacogenetic disorder inherited primarily in an autosomal dominant pattern.
- MH susceptibility is linked to 230 mutations in the skeletal muscle ryanodine receptor (RyR1) and four mutations in the calcium voltage-gated channel subunit alpha1 S (CACNA1S) genes that encode two Ca^{2+} channels necessary for skeletal muscle excitation-contraction coupling.
- Physical interactions between L-type Ca^{2+} channel ($Ca_v1.1$) and RyR1 tightly regulate initiation and termination of skeletal muscle excitation-contraction coupling.
- Skeletal muscle accounts for approximately 40% of body weight and inherent changes in its metabolism have profound impacts on whole-body metabolism and physiology.
- Carriers of MH mutations can exhibit mild to moderate muscle impairments in the absence of triggering agents but are rarely diagnosed.
- Carriers of MH mutations are susceptible to anesthetic-triggered runaway skeletal muscle metabolism, which if not promptly treated is lethal.
- Signs of MH, including increased end-tidal CO_2, increased core temperature, muscle rigidity, tachycardia, and more, are consequences of the fulminant hypermetabolic crisis.
- Exposure to triggering agents or heat stress leads to acute loss of RyR1/$Ca_v1.1$ channel regulation, rapid accumulation of Ca^{2+} within the sarcoplasm, and a hypermetabolic crisis that stimulates adenosine triphosphate (ATP) utilization by pumps attempting to restore resting Ca^{2+} balance among sarcoplasmic reticulum, mitochondrial, and extracellular compartments.
- Dantrolene markedly attenuates myoplasmic calcium (Ca^{2+}) concentrations and thereby restores resting Ca^{2+} balance and metabolism, with reversal of clinical signs.
- Evaluation of persons susceptible to MH includes an in vitro contracture test (IVCT) and caffeine/halothane contracture test (CHCT), and evaluation of DNA to identify mutations.
- Currently DNA testing alone can be used to evaluate 42 human mutations and all swine, equine, and canine MH.
- Future MH goals include advancement of genetic evaluations in North American and European medical programs and stronger finances to support genetic studies, the identification of the mode of action of dantrolene, a determination of the immediate cause of triggering MH, and the development of effective, noninvasive tests for MH susceptibility.
- The absence of mutations in dystrophin, along with dystrophin-associated glycoproteins, is involved in sarcolemmal stability. Its defects are responsible for Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD).
- Whereas the risk for an MH mutation in DMD and BMD patients is similar to that in the general population, the incidence of MH-like anesthetic events has been reported to be 0.002 with DMD and 0.00036 with BMD.
- Succinylcholine is contraindicated in DMD and BMD patients because of the risk of rhabdomyolysis and hyperkalemia as a result of their unstable sarcolemmal membrane.
- Reversal of neuromuscular blockade with sugammadex is a practical alternative to the management of many of these disorders, if rocuronium or vecuronium is used. The combination of rocuronium and sugammadex has improved the anesthetic management for some of these challenging disorders.

Malignant Hyperthermia

Malignant hyperthermia (MH) is one of the most devastating anesthesia-related complications. The fulminant MH syndrome is elicited by the administration of triggering anesthetic agents, such as volatile halogenated anesthetics or depolarizing neuromuscular blocking agents (NMBAs). MH has been and continues to be a life-threatening complication of anesthesia if the diagnosis is not made promptly and treatment is not begun in a timely fashion. Unlike other disorders described in this chapter, MH has virtually no characteristic phenotype before exposure to the triggering agent and is truly an example of the interaction of genes and the environment. Also covered in this chapter are some of the neuromuscular disorders, although rarely encountered in a routine anesthetic practice. This group of disorders challenges both perioperative management and intensive care. They affect the normal function of peripheral nerves, the neuromuscular junction, and/or muscles. Although such diseases are thought to be rare, the number of patients that a clinician may encounter is increasing because of better medical care, increasing longevity, and other possible unidentified factors. Neuromuscular disorders have significant potential to interact with an improper anesthetic plan, and all affected patients require special perioperative attention for anesthetic management. In this area, the armamentarium of invasive and noninvasive diagnostic tools is being developed, especially in genetics.

MH is a pharmacogenetic clinical syndrome that, in its classic form, occurs during anesthesia with volatile halogenated alkanes such as halothane, isoflurane/sevoflurane, /desflurane, and/or administration of the depolarizing muscle relaxant succinylcholine. The fulminant MH episode observed clinically produces muscle hypermetabolism with rapidly increasing body temperature, by as much as 1°C in 5 minutes, and extreme acidosis as a result of acute loss of control of intracellular ionized calcium (Ca^{2+}). It is the sustained high levels of sarcoplasmic Ca^{2+} that rapidly drives skeletal muscle into a hypermetabolic state that may proceed to severe rhabdomyolysis. Although MH was initially associated with a mortality rate of 60%, earlier diagnosis and the use of dantrolene have reduced the mortality to less than 1.4%.[1] Current cases of MH are restricted in severity because of diagnostic awareness, early detection through end-expired carbon dioxide (CO_2), the use of less potent anesthetic triggers, and prior administration of drugs that attenuate the progression of the fulminant episode. Estimates of the incidence of fulminant MH vary widely from one case per 10,000 to 1:250,000 anesthetics administered.[2] The prevalence of MH events in Japan was calculated to be between 1:60,000 and 1:73,000.[3,4] However, the prevalence of MH mutations within kindred known to transmit MH-susceptibility (MHS) mutations may be as high as 1:2000.[5] Males appear to be more susceptible to developing a clinical MH episode than females.[3,6] A gender difference in MHS has also been demonstrated in knock-in mice expressing human MH mutation RyR1-T4825I.[7] The pediatric population accounts for 52.1% of all MH reactions.[8,9]

Between 50% and 80% of genotyped patients who have had a clinical MH syndrome and a positive muscle biopsy have had their disease linked to one of more than 230 mutations in the type 1 ryanodine receptor (RyR1; sarcoplasmic reticulum [SR] Ca^{2+} release channel) gene and four mutations in L-type Ca^{2+} channel ($Ca_V1.1$), the pore subunit of the slowly inactivating L-type Ca^{2+} channel encoded by Calcium Voltage-Gated Channel Subunit Alpha1 S (CACNA1S) (also referred to as the dihydropyridine receptor [DHPR]).[10] The genetics of MHS and the related abnormal function of RyR1, the DHPR, and associated proteins are being investigated at the molecular biologic level, with a porcine model and several new mouse models providing intricate details about the etiology of the disorder. Parallel studies in humans are limited by scarce material for scientific study and are complicated by the fact that phenotypes within a single genotype vary as a result of sex, age, genetic, epigenetic, and environmental modifiers.

Public education and communication in the United States are provided by Malignant Hyperthermia Association of the United States (MHAUS, 11 E. State Street, P.O. Box 1069, Sherburne, NY 13460, U.S.A.; telephone: (+1) 607-674-7901; fax: (+1) 607-674-7910; e-mail: info@mhaus.org; website: http://www.mhaus.org), and by emergency consultation with the MH Hotline (1-800-MHHYPER, or 1-800-644-9737). The North American Malignant Hyperthermia Registry (NAMHR), a professional subsidiary of MHAUS, collates findings from muscle biopsy centers in Canada and the United States (NAMHR, 1345 SW Center Drive, P.O. Box 100254, Gainesville, FL 32610, U.S.A.); telephone: (+1) 888-274-7899; fax: (+1) 352-392-7029.; website http://anest.ufl.edu/namhr/).

HISTORY

Between 1915 and 1925, one family experienced three anesthetic-induced MH deaths with rigidity and hyperthermia and was puzzled for decades regarding the cause of these deaths.[11,12] MHS was eventually confirmed in three descendants by in vitro muscle biopsy tests.[11] In 1929, Ombrédanne described anesthesia-induced postoperative hyperthermia and pallor in children accompanied by significant mortality but did not detect any familial relationships.[13] Critical worldwide attention to MH began in 1960 when Denborough and associates reported a 21-year-old Australian with an open leg fracture who was more anxious about anesthesia than about surgery because 10 of his relatives died during or after anesthesia.[14] Denborough and colleagues initially anesthetized him with the then-new agent halothane, halted it when signs of MH appeared, successfully treated the symptoms, aborted the syndrome, and subsequently used spinal anesthesia. Further evaluations by George Locher in Wausau, Wisconsin, and Beverly Britt in Toronto, Canada, led to the discovery that MH risk was indeed familial.[15] It was also found that the cause of the syndrome was the result of skeletal muscle involvement rather than central loss of temperature control by the recognition of increased muscle metabolism or muscle rigidity early in the syndrome, low-threshold contracture responses, and elevated creatine kinase (CK) values.[16]

Interestingly, a similar syndrome was discovered in swine inbred with breeding patterns designed to produce a rapid growth rate and superior muscle development (e.g., Landrace, Piétrain, Duroc, and Poland China). *Porcine stress syndrome*,[17] which is associated with increased metabolism, acidosis, rigidity, fever, and death from rapid deterioration of muscle and results in pale, soft, exudative pork,[18] can be triggered by any stress, such as separation, shipping conditions, weaning, fighting, coitus, or preparation for slaughter, and had become a significant problem for meat production. In 1966, Hall and coworkers reported that a syndrome that appeared to be identical to MH could be induced in stress-susceptible swine by the administration of halothane and succinylcholine.[19] The cause of this syndrome in pigs was discovered to be a single missense mutation in RyR1, and all susceptible swine have the same Arg615Cys mutation in the SR calcium release channel RyR1.[20]

In 1975, Harrison described the efficacy of dantrolene in preventing and treating porcine MH,[21] which was rapidly confirmed in humans by a multihospital evaluation of dantrolene used to treat anesthetic-induced MH episodes.[22] Today, dantrolene still remains the primary pharmacologic approach for successful MH therapy.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF EXCITATION-CONTRACTION COUPLING AND MALIGNANT HYPERTHERMIA

MH is a syndrome caused by dysregulation of excitation-contraction (EC) coupling in skeletal muscle. Normal muscle contraction is initiated by nerve impulses arriving at the neuromuscular junction (i.e., the motor end plate) that trigger the release of acetylcholine from the nerve terminal. Acetylcholine activates nicotinic cholinergic receptors (nAChR), nonselective cation channels located at the postsynaptic neuromuscular junction, that are essential for local depolarization of the surface muscle membrane (sarcolemma) and initiating action potentials that propagate rapidly along the sarcolemma of muscle cells. Invaginations of the sarcolemma (termed transverse or T tubules) act as conduits to rapidly and uniformly direct-action potentials deep within the myofibrils where they transduce a conformational change in the "voltage sensor" protein $Ca_V1.1$. A central T-tubule is flanked on both sides by a terminal cisternae element from the SR that contains the Ca^{2+} release channels (RyR1). Conformational changes in $Ca_V1.1$ residing within the T-tubule are mechanically transmitted to RyR1 residing in the junctional face of the SR. More specifically, physical coupling of four $Ca_V1.1$ (dihydropyridine receptor) units to every second RyR1 channel form linear arrays at specialized junctions (*triadic junctions*) that are essential for linking electrical signals at the T tubules with the release of Ca^{2+} stored within the SR. Release of SR Ca^{2+} causes the free, cytoplasmic (sarcoplasmic) Ca^{2+} concentration to increase from 10^{-7} M to about 10^{-5} M. This released Ca^{2+} binds to contractile proteins (troponin C and tropomyosin) in the thin filament to expose myosin's actin binding sites which allow shortening and force development by the muscle fibers (i.e., muscle contraction). The entire process is termed excitation-contraction coupling (EC coupling) Intracellular Ca^{2+} pumps (i.e., sarcoplasmic/endoplasmic reticulum Ca^{2+}-adenosine triphosphatase [ATPase], or SERCA) rapidly sequester Ca^{2+} back into the SR lumen, and muscle relaxation begins when the Ca^{2+} concentration falls below 10^{-6} M and ends when the resting sarcoplasmic Ca^{2+} concentration is restored to 10^{-7} M. Because both contraction and relaxation are energy-related processes that consume adenosine triphosphate (ATP), knowing the molecular events contributing to EC coupling and the subsequent relaxation phase is essential to understanding the cause of MH (Fig. 35.1). Clinical and laboratory data from humans, swine, and mice with knock-in mutations indicate that the fulminant MH syndrome is associated with a persistent increase in the concentration of sarcoplasmic Ca^{2+}.[23-26] The increased activity of pumps and exchangers trying to

Fig. 35.1 Key ion channels involved in neuromuscular transmission and excitation-contraction coupling. Nerve impulses arriving at the nerve terminal activate voltage-gated Ca^{2+} channels (1). The resulting increase in cytoplasmic Ca^{2+} concentration is essential for the exocytosis of acetylcholine. Binding of acetylcholine to postsynaptic nicotinic cholinergic receptors (nAChR) activates an integral nonselective cation channel that depolarizes the sarcolemma (2). Depolarizing the sarcolemma to threshold activates voltage-gated Na^+ channels (3), which initiates action potential impulses that propagate deep into the muscle through the transverse tubule system. Within the transverse tubule system, L-type voltage-gated Ca^{2+} channels sense membrane depolarization and undergo a conformational change (4). A physical link between these voltage sensors and the ryanodine receptor (RyR1) sarcoplasmic reticulum Ca^{2+} channel is the means by which the electrical signal is transferred from the T tubule to Ca^{2+} release from the sarcoplasmic reticulum (5). (Modified from Alberts B, Bray D, Lewis J, et al. *Molecular Biology of the Cell*. 3rd ed. New York: Garland Press; 1994.)

correct the increase in sarcoplasmic Ca^{2+} associated with triggered MH increases the need for ATP, which in turn produces heat. Thus the common etiological feature of the disorder is hyperthermia. The rigidity that is frequently seen during a fulminant MH episode is the result of the inability of the Ca^{2+} pumps and transporters to reduce the unbound sarcoplasmic Ca^{2+} below the contractile threshold (10^{-6} M). Dantrolene is an effective therapeutic for treatment of fulminant MH because it reduces the concentration of sarcoplasmic Ca^{2+} to below contractile threshold. However, the pathway by which dantrolene lowers sarcoplasmic Ca^{2+} is complex and still not fully understood. Dantrolene's ability to suppress Ca^{2+} release from SR appears to depend on elevated sarcoplasmic Mg^{2+} concentration[27]; however the drug also attenuates depolarized-triggered Ca^{2+} entry mediated by $Ca_V1.1$, which is exacerbated in MHS muscle cells and MH normal muscle cells exposed to ryanodine.[28] Thus whether dantrolene directly inhibits RyR1 or requires additional intermediates within the triad junctions remains to be clarified.

Malignant Hyperthermia Is the Result of Abnormal Function of Muscle Calcium Release Units

RYANODINE RECEPTORS

Ryanodine receptors (RyRs) within the muscle are synonymous with the junctional foot protein/SR calcium release channel, and are so named because they specifically bind the toxic plant alkaloid ryanodine, which can activate or inhibit the channel depending on its concentration.[29,30] In all mammals there are three RyR isoforms. In humans, they are encoded by three genes located on chromosomes 19q13.1,[31] 1q42.1-q43,[32] and 15q14-q15,[33] for the "skeletal" (RyR1), "cardiac" (RyR2), and "brain" (RyR3) isoforms, respectively. Each functional RyR is a homotetramer consisting of four identical subunits (~5000 amino acids each), and an accessory protein, calstabin 1 (FK506 12-kd binding protein [FKBP12]).[34-37]. The total mass of the tetramer exceeds 2 mega-Daltons. Thus it is one of the largest known proteins and the largest known channel in mammalian species. Evidence of direct coupling of $Ca_V1.1$ and RyR1 has been demonstrated both by expressing chimeric $Ca_V1.1/Ca_V1.2$ cDNA in dysgenic myotubes that lack constitutive expression of $Ca_V1.1$[38,39] and chimeric RyR1/RyR2/3 cDNA in dyspedic myotubes that lack constitutive expression of RyR1, 2, and 3. Such studies have provided compelling evidence that the cytoplasmic region between repeats II and III (i.e., cytosolic II-III loop) of $Ca_V1.1$ contains a stretch of 46 amino acids (L720 to Q765) and multiple regions of RyR1 that are essential for engaging bidirectional signaling between $Ca_V1.1$ and RyR1.[40-42]

In the last two decades, our understanding of EC coupling has increased significantly by identifying protein-protein interactions that regulate both the release and sequestration of Ca^{2+} within skeletal muscle. The elemental unit of function has been named the Ca^{2+} release unit (CRU), and it is localized within junctional regions of T-tubule and SR membranes.[43] The CRU is a macromolecular assembly of interacting proteins that participate in regulating EC coupling. RyR1 is a high-conductance channel that regulates release of SR Ca^{2+} and is the central component of the CRU. The functional RyR1 tetramer anchored within the SR membrane physically spans the junctional space to interact with tetrads composed of four voltage-activated $Ca_V1.1$ subunits within the T-tubule membrane. This physical interaction engages a form of bidirectional signaling that tightly regulates the function of both proteins. Moreover, interaction of $Ca_V1.1$ and RyR1 does not occur in isolation, but are further subject to regulation by a number of proteins localized within the triad junction, including Homer 1, which physically binds and functionally couples target proteins, calstabin 1, triadin, junctin, Mg29, junctophilin 1 and 2, calsequestrin, calmodulin, STAC 3, the catalytic and regulatory subunits of protein kinase A, and protein phosphatase 1.[44-50]. It is likely that this list is not complete and that there are other critical components which make up this tightly regulated macromolecular complex. More importantly, there is increasing experimental evidence that mutations found in RyR1 ($_{MH}$RyR) or $Ca_V1.1$ ($_{MH}Ca_V1.1$) can alter protein-protein interactions in the CRU,[51-53] as well as alter the functional fidelity of bidirectional signals.[54-58]

In the presence of certain chemical substances, MH mutations in RyR1 or DHPR cause severe dysregulation of RyR1 channel function. This can be seen in vitro as a heightened sensitivity to volatile anesthetics, 4-chloro-*m*-cresol, caffeine, ryanodine, and potassium depolarization.[59-61] Chemically induced dysfunction of the RyR1 complex appears to be the principal cause of triggering uncontrolled skeletal muscle metabolic acidosis (aerobic and glycolytic), rigidity, and hyperkalemia, but the mechanisms governing the syndrome are unclear. Also unclear is the relationship among exertional heat illness, exertional rhabdomyolysis, and MHS, an area that requires more investigation and, if possible, controlled clinical studies.[62]

Two essential cations greatly shape the kinetics and magnitude of Ca^{2+} release in response to depolarizing triggers: Ca^{2+} itself and Mg^{2+}. The normal RyR1 complex responds to Ca^{2+} in a biphasic manner. First, Ca^{2+} activates the channel in a graded manner between 100 nM and 100 μM, whereas higher concentrations inhibit channel activity.[63,64] This biphasic action is thought to occur via binding of Ca^{2+} to two classes of regulatory sites on RyR1, a high-affinity stimulatory site and a low-affinity inhibitory site.[46] Mg^{2+}-induced inhibition is the second important physiologic regulator of RyR1 activity in skeletal muscle.[65,66] Mg^{2+} inhibits RyR1 in a cooperative manner ($n_H \approx 2$; 50% inhibitory concentration [IC_{50}] ≈ 650 μM). It is likely that Mg^{2+} acts by competing with Ca^{2+} at its activator sites and by binding to yet unidentified low-affinity inhibitory sites.[67,68] It is possible that MH mutations introduce allosteric instability into the RyR1 complex which leads to a reduction of inhibition rather than directly altering the binding properties of Ca^{2+} or Mg^{2+}, or both, at the activator or inhibitor sites. Therefore hypersensitivity to pharmacologic agents is likely to be closely tied to altered responses to physiologic ligands. However, whether MHS channels are primarily hyposensitive to inhibition by Mg^{2+} or Ca^{2+} (or both),[69,70] are hypersensitive to activation by Ca^{2+}, or exhibit altered sensitivities in both directions to both ions seems to be highly dependent on the location of the MH mutation.[71,72] Studies have also pursued the "leaky channel" hypothesis by examining

SR preparations from homozygous R615C MHS pigs and heterozygous R163C and C512S mice. They observed a significantly lower Ca^{2+} loading capacity (38%, 23%, and 22% lower than matched wild type mice, respectively) primarily mediated by the presence of leaky channels that remain active even with 100 nM extravesicular Ca^{2+}.[73,74] Recent studies indicated that expression of $Ca_V1.1$ represses the basal activity of the ryanodine-insensitive RyR1 leaky state.[56] It is important that MHS mutations appear to not only alter bidirectional signaling during EC coupling [57,58] and inherent regulation of RyR1 channel functions,[71,72] but also weaken negative regulation conferred by $Ca_V1.1$ on RyR1 Ca^{2+} leak under nontriggering conditions.[54] These findings at the molecular and cellular level using knock-in MHS mice confirm earlier measurements made in porcine and human MHS muscles, myotubes, and myoball preparations and in dyspedic myotubes expressing $_{MH}$RyR1 cDNAs, all of which have been shown to have chronically elevated resting cytoplasmic $[Ca^{2+}]_i$.[53,60,75]

Results from both functional and structural evidence suggests that long-range interdomain interactions between regions of RyR1 are involved in channel regulation by stabilizing protein conformations critical for normal channel transitions.[76] A three-dimensional reconstruction of RyR1 by Samso and coworkers shows that the RyR1 architecture is designed to support long-range allosteric pathways such as coupling with $Ca_V1.1$ and binding to ligands such as calmodulin and FKBP12.[77] This structural model for gating has been recently confirmed at molecular scale resolution by several laboratories.[78]

VOLTAGE-GATED CALCIUM CHANNELS: ROLE OF $CA_V1.1$

Although the majority of mutations that confer MHS reside in the RyR1 gene, three mutations in the *CACNA1S* gene encoding for the $Ca_V1.1$ subunit of skeletal muscle have been linked to human MHS.[5,79-81] The Arg1086His mutation in the intracellular loop connecting homologous repeats III and IV of $Ca_V1.1$ represented the first MH-causing mutation so far identified in a protein other than RyR1. Physiological characterization of the R1086H mutation further demonstrated that sensitivity of RyR1 activity was significantly enhanced by membrane depolarization or by pharmacologic activators of RyR1 (e.g., caffeine).[82] In addition, Pirone and associates have identified an MHS-causing Thr1354Ser mutation in the S5-S6 extracellular pore-loop region of the homologous repeat IV of $Ca_V1.1$ Expression of the T1354S mutation also accelerated L-type Ca^{2+} current kinetics and also contributed to an increase in RyR1-mediated Ca^{2+} release.[81] The Arg174Trp $Ca_V1.1$ MH mutation occurs at the innermost basic residue of the IS4 voltage-sensing helix, a residue conserved among all Ca_V channels. Unlike the other $Ca_V1.1$ MHS mutations, homozygous expression of R174W completely ablates the L-type current, but despite this, has no influence on normal EC coupling. In murine studies, muscle fibers from Het R174W animals verify the increased sensitivity of Ca^{2+} release to caffeine and halothane compared with myotubes expressing wild type $Ca_V1.1$,[54,83] but whether this mutation is sufficient to confer anesthetic- or heat-triggered fulminant MH remains to be tested.

FACTORS OTHER THAN RYANODINE RECEPTOR ABNORMALITIES

Other cellular processes can affect MH episodes. It has been demonstrated that concurrent administration of nondepolarizing neuromuscular blocking drugs at the same time as triggering agents can delay or prevent the onset of clinical MH syndrome. Pretreatment of MHS pigs with sufficient nondepolarizing neuromuscular blocking agent, which is used to completely abolish muscle twitch elicited by electrical stimulation of the nerve, prevented halothane from triggering the clinical syndrome for 90 minutes, the longest time point tested.[84] However, in the continued presence of halothane, when function of the neuromuscular junction was restored by administration of the cholinesterase inhibitor neostigmine, clinical MH was triggered immediately. This suggested a close relationship between functional neuromuscular junctions or depolarization of the sarcolemma (or both) and the clinical syndrome.

In myotubes, sarcolemmal excitation-coupled Ca^{2+} entry (ECCE) is sensitive to the conformation of the RyR1 and is enhanced by several mutations in RyR1, including MH mutations.[44,52,85] ECCE appears to be an inherent property of $Ca_V1.1$ during long or repetitive depolarization of myotubes,[86] possibly mediated by shifting $Ca_V1.1$ to the mode 2 gating conformation. Nevertheless, enhanced ECCE in MHS muscle may contribute to an increased sensitivity to depolarization and appears to be one target for dantrolene's abrogation of responses to both electrical and potassium chloride depolarization.[51] Although CACNA1S expression undergoes developmental switching to a splice variant that downregulates Ca^{2+} current density of $Ca_V1.1$ channels in adult fibers, mutations that maintain Ca^{2+} current density more similar to those measured with embryonic myotubes has recently been shown to promote muscle pathology.[87]

In addition to ECCE, classic store-operated capacitive Ca^{2+} entry pathways similar to the store-operated Ca^{2+} entry (SOCE) seen in nonexcitable cells[88] have been shown to be present in skeletal muscle[89-91] and appear to be more active in MHS muscles both at rest as a response to chronic store depletion and during an MH crisis. These SOCE channels have also been suggested to be a target for dantrolene, but this has not been validated by other studies.[92] Together, these data suggest that $_{MH}$RyRs or $_{MH}Ca_V1.1$ assume a conformation that enhances Ca^{2+} entry via ECCE or SOCE (or both). This enhanced entry, when combined with decreased sensitivity of $_{MH}$RyRs to Ca^{2+} and Mg^{2+} inhibition, could provide cellular conditions that heighten sensitivity to triggering agents and perpetuate the fulminant clinical MH syndrome.

DANTROLENE

Dantrolene is the only medication that has been shown to be effective in reversing the symptoms of MH. Preadministration of dantrolene will also prevent the development of fulminant MH in homozygous pigs or MH mice when exposed to a triggering stimulus. Dantrolene sodium is a hydantoin derivative (1-[5-(4-nitrophenyl)-2-furanyl]methylene] imino]-2,4-imidazolidinedione) that does not block neuromuscular transmission, but causes muscle weakness by direct muscular action. The properties of dantrolene have been closely correlated with its ability to reduce efflux of Ca^{2+} from the SR in vitro.[93] Dantrolene (20 μM) counteracts the effect of reduced Mg^{2+} inhibition in MH-affected muscle.[94] Dantrolene (20 μM) can inhibit the enhanced sensitivity to caffeine seen in MH muscles, and both dantrolene and its more water-soluble analog azumolene (150 μM) have been shown to reduce depolarization-induced release of Ca^{2+}, both in muscle and in triadic vesicles.[95] The idea that dantrolene suppresses SR Ca^{2+} release as a result of direct interactions with RyR1 is somewhat controversial. Paul-Pletzer and associates demonstrated that [^{3}H]azidodantrolene specifically labels the amino terminus of RyR1 defined by the 1400-amino acid residue N-terminal calpain digestion fragment of RyR1.[96] More detailed analysis further localized the [^{3}H]azidodantrolene binding site to a single domain containing the core sequence corresponding to amino acid residues 590 through 609 of RyR1.[96] However, to date, we lack evidence of a direct action of dantrolene on single RyR1 channels studied in lipid bilayers, even though they are reconstituted with calstabin 1, ATP, and activating concentrations of Ca^{2+}, which suggests that dantrolene's main action is to alter key protein-protein interactions. The recent discovery that inhibition of SR Ca^{2+} release by dantrolene requires Mg^{2+} may help resolve the controversy of the conflicting observations on dantrolene inhibition of RyR1 channel activity in Mg^{2+}-free bilayer experiments.[27]

Genetics

RyR1 mutations have been found in 50% to 80% of patients and relatives who are labeled MHS by positive contracture tests and in almost all families with central core disease (CCD) and King-Denborough syndrome (KDS). More than 210 missense mutations and 8 deletions associated with MH have thus far been detected. Another 29 missense mutations are associated with CCD and multiminicore disease (MmD) in patients with unknown MH testing status.[10] Interestingly, 40% of missense *RyR1* mutations occur at CpG dinucleotide sequences. Five other loci (17q21-24, 1q32, 3q13, 7q21-24, and 5p) have been linked to families with both positive contracture tests and an unusual response to anesthesia, and have been designated MHS loci 2 through 6, respectively. However, of these five, the only gene that has been shown to be associated with MH is *CACNA1S*,[97] which codes for Ca$_V$1.1 (the α_{1S}-subunit of DHPR) in the MHS3 locus. Two causative mutations in this gene are linked to less than 1% of MHS families worldwide. In some of the other loci, all genes within the locus have been ruled out as causing susceptibility to MH. Hence for practical reasons, the *RyR1* gene remains the primary target for current clinical genetic analysis.

DISTRIBUTION OF *RyR1* MUTATIONS

The missense mutations associated with MHS, CCD, or, in some cases, both, are dispersed throughout the coding region of the *RyR1* gene, and all allow transcription of a protein that is putatively functional.[10,98] Until recently, it was thought that most *RyR1* mutations were clustered in three "hot spots:" between amino acid residues 35 and 614 (MH/CCD region 1), between amino acid residues 2163 and 2458 (MH/CCD region 2) in the sarcoplasmic foot region of the protein, and between amino acids 4643 and 4898 in the carboxyl-terminal transmembrane loop or pore region (MHS/CCD region 3) (Fig. 35.2).[99] It appears that the supposition that there were "hot spots" was simply due to bias in sample analysis inasmuch as the missense mutations associated with MH or CCD (or both) are scattered over 54 of the 107 exons of *RyR1*. Approximately 41% of reported MH

Fig. 35.2 Schematic representation of the triad junction of skeletal muscle shows the junctional foot protein (ryanodine [RyR1] receptor) and its associated proteins. In skeletal muscle, the α_{1S}-subunit of the dihydropyridine receptor *(DHPR)* participates in excitation-contraction coupling. These physical links transmit essential signals across the narrow gap of the triadic junction that activate the RyR1 and release Ca^{2+} from the sarcoplasmic reticulum. (Modified from Pessah IN, Lynch C III, Gronert GA: Complex pharmacology of malignant hyperthermia. *Anesthesiology* 1996;84:1275.)

mutations are found in multiple families. CCD mutations are predominantly found in the C-terminal region of the gene (exons 85-103), and only 10 mutations (17%) have been described in more than one family: R4861H ($n = 14$), V4849I ($n = 9$), I4898T ($n = 7$), L4824P ($n = 4$), A4940T ($n = 4$), G4638D ($n = 3$), R4893W ($n = 3$), R4861C ($n = 2$), R4893Q ($n = 2$), and G4899E ($n = 2$).

The true ethnic distribution of MH and CCD is difficult to ascertain. MH and CCD have been reported in Western populations predominantly, but this is likely the result of the manner and frequency in which cases are reported. It does appear that some mutations are clustered in a given region of the world, but the distribution and frequency appear to be somewhat population specific. In the United Kingdom, 69 *RyR1* mutations have been discovered, 25 of which are found only in a single family. G2434R is found in approximately 40% of the 434 mutation-positive MH families investigated in the United Kingdom, with the next most common mutations being T2206M (10%) and G341R (8%). In Switzerland, V2168M and I2336H are the predominant mutations,[100] and in Germany, R163C (MH and CCD), R614C (MH), T2206M (MH), G2434R (MH), and R2454H (MH) have each been detected in five or more independent cases.[101,102] G341R and R614C are common in France,[103] and R614C has also been found in several MH families from Italy[103] and Canada.[104] G341R has been found frequently in Belgium.[103] The mutation common to Europe and North America is G2434R, which occurs in 4% to 7% of European and 5.5% of North American families.[105] Single-family mutations are the most common mutations reported in Japanese, Chinese, Taiwanese, Australian, and New Zealand MH families with the exception of the R163C mutation reported in a large population in rural New South Wales in Australia and the T4826I mutation which is found in numerous families in the Maori population of New Zealand.[106-108] However, despite these two exceptions, it is likely that the reason for unique family mutations in Asia and Australasia may reflect the small number of cases investigated there. Because genetic screening in European and North American studies has predominantly targeted only regions 1 and 2 of the original hot spots in the gene, the absence of *RyR1* mutations in some of the screened population could be explained by *RyR1* mutations located outside these two regions or by involvement of other genes.

INHERITANCE AND PENETRANCE OF MALIGNANT HYPERTHERMIA

Inheritance of human MH can no longer be considered to be solely autosomal dominant with variable penetrance because more than one MH-linked mutation has been identified in some probands and families. Six non-consanguineous families harbor at least two *RyR1* mutations that have both been linked to MHS, and in two of those families, one is an *RyR1* mutation and the second is a $Ca_V1.1$ mutation.[5] Although MHS homozygotes are common in affected pigs, they are rare in humans and only found in 50% of currently available transgenic mouse populations. The known MHS homozygous humans also appear clinically normal, but exhibit stronger responses to in vitro contracture test (IVCT) and caffeine/halothane contracture tests (CHCTs) than heterozygous individuals do.[109-112] Homozygosity of two MH mutations in "hot spot" 1 leads to perinatal lethality in mice.[73,74] Double heterozygous individuals do not appear to show any additive effect of the second mutation on IVCT.[5]

IN VITRO CONTRACTURE TEST AND CAFFEINE HALOTHANE CONTRACTURE TEST

The gold standard for diagnosis of MH is the halothane and caffeine muscle contracture test, also known as the IVCT or the CHCT. There are two protocols developed by the European Malignant Hyperthermia Group (EMHG) and the North American Malignant Hyperthermia Group (NAMHG), respectively.[9] The two protocols are similar, but not identical. For the purpose of differentiation, we designate IVCT to the EMHG protocol and CHCT to the NAMHG protocol.

For IVCT, the muscle biopsy will be performed on the quadriceps (either vastus medialis or vastus lateralis)[113,114] and consists of three parts: a static caffeine test, a static halothane test, and a dynamic halothane test.[114] For the static caffeine test, a stepwise increased concentration (0.5, 1, 1.5, 2, 3, 4, and 32 mmol/L) is applied. The lowest concentration of caffeine which produces a sustained increase of at least 0.2 g in baseline tension is reported as the caffeine threshold. Then, the halothane threshold is obtained using the same method by exposing the muscle to halothane concentrations of 0.5%, 1%, 2%, and 3% v/v. The dynamic halothane test is performed with the muscle stretched at a constant rate of 4 mm/min to achieve a force of approximately 3 g and held at the new length for 1 min for a 3 min exposure to halothane. For each cycle, halothane concentration will be increased from 0.5%, 1%, 2%, to 3% v/v: volume (solute) per volume (solvent). The concentration of halothane which produces a sustained increase of at least 0.2 g in the muscle tension compared to the pre-halothane control is defined as the dynamic halothane threshold.[114] The IVCT protocol classifies the patients into three groups: MH Susceptible (MHS_{HC}) group with a caffeine threshold at the caffeine concentration of 2 mmol or less and a halothane threshold of 2% v/v halothane or less; MH Normal (MHN) group with a caffeine threshold at the caffeine concentration of 3 mmol or more without a halothane response at 2% v/v; MHS_H and MHS_C groups which describe individuals that used to be classified as MHE (equivocal) who are only responsive to either halothane or caffeine alone.[113,114] The MHE descriptor was dropped because use of the 'equivocal' label outside of its laboratory context has the potential to confuse patients and clinicians unfamiliar with its derivation.[115]

For CHCT, a muscle biopsy can be taken from the following sites in the order of preference: (1) the vastus group, (2) the rectus abdominis, and (3) other muscle groups under special circumstances.[116] Required tests include exposure of muscle to 3% v/v halothane alone and to incremental caffeine concentrations (0.5, 1, 2, 4 mmol, and 8.0 mmol if the response at 4 mmol is <1 g, and 32 mmol) alone. Optional tests include exposure of muscle to a combination of both 1% halothane and incremental caffeine concentrations, and to 2% v/v halothane alone.[116] According to CHCT protocol, an individual is MHS when either of the halothane or the caffeine test is positive, and MHN when both tests are negative.[116]

The sensitivity of IVCT was reported to be 99.0% (95% confidence interval [CI] 94.8%-100%) if the MHE group is considered susceptible and the specificity of IVCT was 93.6% (95% CI 89.2%-96.5%),[114] while the sensitivity and specificity of CHCT was 97% (95% CI 84%-100%) and 78% (95% CI 69%-85%), respectively.[117] Recently, fluoroquinolones and statins, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, were found to induce significant contractures in MHS muscle bundles, but not in MHN.[118,119] Ondansetron and 3,4-methylenedioxymethamphetamine (MDMA) may also dose-dependently induce contracture or increase the sensitivity of the contractile apparatus to calcium in both MHS and MHN fibers.[120,121] Modifications to the IVCT protocol by adding ryanodine[122] or 4-chloro-*m*-cresol,[114,123] a RyR-specific agonist, has been reported, but has not been included in the standard protocol. Furthermore, Metterlein and associates studied the possibility of replacing halothane with newer volatile agents in IVCT. At increasing concentration, except for sevoflurane, all newer volatile agents, including enflurane, isoflurane, and desflurane, induced significantly greater contractures in MHS muscle compared to MHN bundles. However, within the MHS muscle bundles, halothane produced significantly higher contractures, and was considered the strongest discriminator for MH using the IVCT protocol.[124] A direct application of high sevoflurane concentration of 8%, instead of the stepwise application, has been shown to induce significantly stronger contractures in MHS subjects.[125] Nevertheless, from the retrospective analysis of the Japanese MH database, there was no evidence between the severity of MH triggered by sevoflurane and isoflurane, or other agents, suggesting sevoflurane is a weak or weaker MH triggering agent.[126]

DISCORDANCE BETWEEN GENETIC AND IN VITRO CONTRACTURE TEST/CAFFEINE/HALOTHANE CONTRACTURE TESTS MALIGNANT HYPERTHERMIA TESTING

Discordance has confounded linkage analysis worldwide. Examples include MHN patients carrying an *RyR1* mutation associated with MH and MHS patients who do not carry the familial *RyR1* mutation. Several explanations are possible, the most likely being that IVCT/CHCT is not clinically precise and that the thresholds for IVCT or CHCT are inexact. This would lead to errors in determining whether a patient was MHN or MHS. A second possibility is variable penetrance with possible allelic silencing,[127] and a third is that individuals with discordance have mutations in other unknown genes or modifier genes that affect the function of *RyR1* and its phenotypic penetrance. The discrepancy between the incidence estimates of MH events and the prevalence estimates also points to possible epigenetic factors at work. Carpenter and associates have suggested that the severity of MHS may be related to the *RyR1* variant and mutation found within the highly conserved regions of *RyR1* gene.[79] The rarity of large kindreds with MH makes linkage analysis and understanding variability in clinical manifestations difficult. Robinson and associates demonstrated by the transmission disequilibrium test that loci on chromosomes 5 and 7 and, to a lesser extent, loci on chromosomes 1 and 7 influence susceptibility to MH.[103]

GUIDELINES FOR GENETIC SCREENING

In 2000, the European MH group (EMHG) formulated guidelines for *RyR1* mutation screening with linkage data to other loci for some MH families, but all MH investigators emphasized the vital role of IVCT in the diagnosis of MH.[128] These guidelines for screening have reduced the number of relatives requiring contracture testing without increasing the risk of misdiagnosis.[129,130] In 2015, the EMHG published a revision of the guidelines for the investigation of MHS. This updated guideline provided a detailed patient referral criteria and clinical interpretation of IVCT results (https://www.emhg.org/testing-for-mh-1).

Only a small number of MHS families have been investigated extensively in North America by phenotyping, linkage analysis, and screening of specific genes. Collaborative protocols over the past several years between MH biopsy centers and molecular biologists have screened 209 unrelated MHS subjects for mutations in the *RyR1* gene (see Distribution of *RyR1* Mutations).

Larach and coworkers reported a 34.8% morbidity rate in 181 MH cases reported to the NAMHR between January 1987 and December 2006. They also reported that the occurrence was more frequent in young males (75%) (median age of 22.0) and 75% of these patients had undergone at least one general anesthetic with no observed signs of MHS.[131] This underscores the complication of determining the prevalence of MHS in the absence of an inexpensive MH diagnostic test.

Fulminant Malignant Hyperthermia

Fulminant MH is rare. Acute episodes of MH depend on four variables: a genetic (perhaps rarely acquired) predisposition, the absence of inhibiting factors, the presence of an anesthetic or nonanesthetic trigger, and the presence of environmental factors that could potentiate the action of one or more of the other three variables.

ANESTHETIC TRIGGERING

Anesthetic drugs that trigger MH include ether, halothane, enflurane, isoflurane, desflurane, sevoflurane, and depolarizing muscle relaxants, the only currently used of which is succinylcholine. Desflurane and sevoflurane appear to be less potent triggers than halothane and produce a more gradual onset of MH.[132,133] The onset may be explosive if succinylcholine is used. MHS swine were traditionally screened by induction with a volatile anesthetic, which led to pronounced hind limb rigidity within 5 minutes, frequently sooner.[134] Prior exercise even an hour before induction of anesthesia increased the severity and hastened the onset of rigidity in swine.[134] Similarly, in the new knock-in mouse models, the onset of limb rigidity after commencing exposure to volatile anesthetics is very rapid. There are also several modifying factors that are more likely to be present in humans than in pigs or mice and can alter (or even prevent) the onset of clinical MH. Mild hypothermia and preadministration of barbiturates, tranquilizers, propofol, or nondepolarizing neuromuscular blockers delay or prevent the onset of MH[25,134-136] in MHS humans, thus making them respond less predictably than swine or MH knock-in mice. There have been many instances in which fulminant MH has been reported in patients who have previously tolerated potent triggers without difficulty.[137] The reason behind why this occurs is unknown, but it is likely to be related to prior or concurrent administration of drugs that prevent or delay onset of the syndrome, as described earlier, or unknown environmental influences that help provoke the positive incident. Thus onset of the syndrome in humans is extremely variable both in initial symptoms and in the time of onset of the syndrome. Its onset is so variable that making the diagnosis in the setting of a clinical anesthetic can be quite difficult. Although not perfect, the clinical grading scale developed by Larach and colleagues[138] is a useful way for clinicians to retrospectively determine whether a patient who responded abnormally to anesthesia is in any way likely to actually have had a clinical MH episode. However, MH is most easily diagnosed prospectively by vigilance, recognizing its signs and symptoms, and knowing how to treat the syndrome.

The two classic clinical manifestations of fulminant MH syndrome may start in one of the following two scenarios.

1. Rigidity after induction with thiopental and succinylcholine, but successful intubation, followed rapidly by the symptoms listed after scenario 2.
2. Normal response to induction of anesthesia and uneventful anesthetic course until onset of the following symptoms:

- Unexplained sinus tachycardia or ventricular arrhythmias, or both
- Tachypnea if spontaneous ventilation is present
- Unexplained decrease in O_2 saturation (because of a decrease in venous O_2 saturation)
- Increased end-tidal PCO_2 with adequate ventilation (and in most cases unchanged ventilation)
- Unexpected metabolic and respiratory acidosis
- Central venous desaturation
- Increase in body temperature above 38.8°C with no obvious cause

The usually muted onset of MH (scenario 2) is in most cases detected quickly by the development of tachycardia, increased levels of expired CO_2, and muscle rigidity. It can be delayed for several reasons and may not be overt until the patient is in the recovery room. Once initiated, the course of MH can be rapid. When clinical signs such as increased expired CO_2, muscle rigidity, tachycardia, and fever suggest MH, more than one abnormal sign must be observed before making the diagnosis because according to a metaanalysis of many reported cases, a single adverse sign does not usually indicate MH.[138] The mechanism by which anesthetics and depolarizing muscle relaxants trigger MH is unsolved, *but* it cannot be ignored that they are etiologic agents and that early diagnosis is critical for successful treatment.

NONANESTHETIC MALIGNANT HYPERTHERMIA

MH can be triggered by stress such as exercise and overheating, known as “awake” MH. Numerous anecdotal reports of MH-like episodes in humans after stressful situations were reported.[139-144] Measurement of plasma catecholamine levels during exercise showed no differences between MHS and normal individuals.[145,146] Therefore it is unlikely that these responses were provoked by sympathetic overdrive or catecholamine surge.[147]

Wappler and associates reported *RyR1* mutations in three of twelve unrelated patients with exercise-induced rhabdomyolysis (ER); and 10 of those same 12 patients produced abnormal contracture response with IVCT.[148] One had an equivocal response. In susceptible swine, environmental stress such as exercise, heat, anoxia, apprehension, and excitement triggers fulminant MH (see History).[9,134] These responses are related to muscle movement or to increased temperature. Increased ambient temperature triggers fulminant MH in four strains of heterozygous MH mice and in two homozygous strains.[74,75] Epidemiologic studies have shown that exercise-induced symptoms, including rhabdomyolysis, may occur more frequently in MHS patients[148]; and an Arg401Cys *RyR1* mutation was present in three cases of exercise-induced rhabdomyolysis.[106] Other reports are largely anecdotal and relate heat stroke, sudden and unexpected death, unusual stress and fatigue, or myalgias to possible “awake” MH episodes. Stresses associated with these episodes include exercise and environmental exposure to volatile nonanesthetic vapors.[141,149,150] In the United States, MHAUS provided recommendations of adverse effects of heat and exercise in relation to MHS.[151]

Malignant Hyperthermia–Associated Syndromes

MASSETER SPASM (“THIOPENTAL-SUCCINYLCHOLINE OR HALOTHANE-SUCCINYLCHOLINE RIGIDITY”)

A masseter spasm or trismus is defined as jaw muscle rigidity in association with limb muscle flaccidity after the administration of succinylcholine. The masseter and lateral pterygoid muscles contain slow tonic fibers that can respond to depolarizing neuromuscular blockers with a contracture.[152,153] This is manifested clinically on exposure to succinylcholine as an increase in jaw muscle tone, and was well defined by van der Spek and associates.[154] There is a spectrum of responses, for example, a tight jaw that becomes a rigid jaw and then a very rigid jaw (Fig. 35.3). This jaw rigidity may occur even after pretreatment with a “defasciculating” dose of a nondepolarizing relaxant. If there is rigidity of other muscles in addition to trismus, the association with MH is absolute; anesthesia should be halted as soon as possible and treatment of MH begun.

However, in more than 80% of patients with trismus but no rigidity of other muscles, it is a variant found in normal patients. If trismus occurs, proper monitoring should include end-expired CO_2, examination for pigmenturia, and arterial or venous blood sampling for CK, acid-base status, and electrolyte levels, particularly potassium. Although scientifically unproven, it is thought that the initial tightness of the jaw and its duration may predict the gravity of the response. MHAUS recommends following CK and urine myoglobin for 36 hours with 6-hour intervals. Patients with masseter spasm should be observed closely for at least 12 hours.

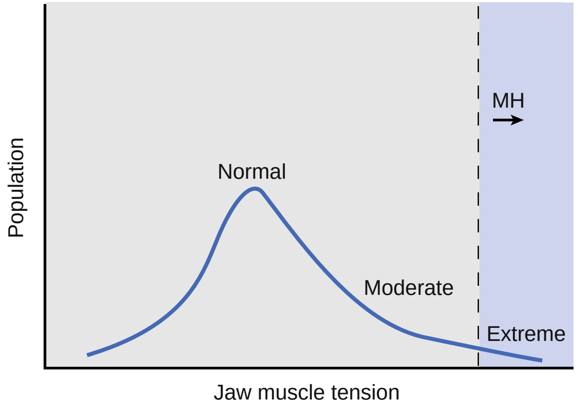

Fig. 35.3 Succinylcholine usually increases jaw muscle tone slightly. In some patients this increase is moderate, and in very few, the effect is extreme (i.e., "jaws of steel"). As many as 50% of this latter group may be susceptible to malignant hyperthermia *(MH)*. Somewhere in the area of the declining curve is the boundary for the MH population.

CORE MYOPATHIES

CCD is a rare hereditary disease. It was first reported in 1956 by Magee and Shy.[155] A recent population study in northern England revealed a prevalence of 1:250,000.[156] In 1971, Engel and colleagues reported a related congenital myopathy, multicore disease.[157,158] Subsequently, various designations of the terms were reported for the variations of the disease, including minicore myopathy and multiminicore myopathy.[157] MmD is now the most official term for these variations sponsored by the European Neuromuscular Centre.[157]

As mentioned, most CCD cases are due to dominant missense mutations in the RyR1 gene. Clinically, CCD patients present with muscle weakness of variable degree and histologically with central cores in the skeleton muscle type I fibers.[159] MmD is considered a recessively inherited myopathy with severe axial weakness, while respirator, bulbar, and extraocular muscles are commonly affected.[159] MmD has a heterogenous genetic association with a recessive mutation in the SEPN1 gene on chromosome 1p36 and in the RyR1 gene.[159] Both type 1 and type 2 fibers may be affected.[157]

Serum CK levels in CCD patients are often normal but may be elevated up to 6 to 14 times in rare cases. Muscle ultrasound often demonstrates increased echogenicity in the quadriceps muscle with relative sparing of the rectus muscle. This characteristic pattern of selective involvement can also be seen on the muscle MRI and has been reported in the patients with typical CCD,[157] which seems to be distinctive to conditions linked to *RyR1* locus.

The relationship between CCD and MHS is complex. A positive IVCT test has been confirmed in many patients with CCD, whereas MHS has been excluded in some. In consideration of the strong link and potential risk, it is advisable to consider all patients with CCD at risk for MH unless the patient has a negative IVCT. Although MHS has not been reported in *SEPN1*-related myopathies, it is prudent to apply a nontriggering approach to MmD patients, given the potential risk in *RyR1*-related MmD. Clinical MH reactions have been reported in MmD patients.[160,161]

KING-DENBOROUGH SYNDROME

To address the KDS, we first introduce Noonan syndrome, an autosomal dominant condition involving the face, cardiovascular, hematological, and skeletal systems. Named after Dr. Jacquline Anne Noonan, a pediatric cardiologist, typical Noonan syndrome features delayed puberty, down-slanting or wide-set eyes, hearing loss, low-set or abnormal shaped ears, mild mental retardation (in about 25% of the cases), ptosis, short statue, small penis and undescended testicles in males, pectus excavatum, and a webbed and short neck. The incidence is 1:1000-1:2500 live births.[162] Fifty percent of the patients have protein-tyrosine phosphatase, nonreceptor-type II (*PTPN2*) mutations.[163] Other genes involved are *SOS1*, *KRAS*, *RAF1*, *BRAF*, *MEK1*, and *NRAS*, and they encode proteins that are part of the Ras (a GTPase)-mitogen activated protein kinase (RAS-MAPK) signaling pathway.[164] Noonan syndrome was recently defined as part of the neuro-cardio-facial-cutaneous syndrome family.[165] An earlier study with a series of 27 patients demonstrated one case of mildly elevated CK despite multiple uneventful cases of general anesthesia with halothane and succinylcholine.[166] Although there is weak evidence for MHS for patients with Noonan syndrome, its resemblances to KDS should raise the concern for the confirmation of the diagnosis. Prevalence of bleeding disorders in Noonan syndrome was reported to be from 20% to 89%,[164] ranging from thrombocytopenia to platelet dysfunction to von Willebrand disease to factor deficiencies. Routine screening including, but not limited to, bleeding history, platelet count, coagulation panel, and factor XI level, was recommended.[165,167] Hematological consultation becomes appropriate if any of these tests are abnormal. The high palatal arch, dental malocclusion, and the webbed neck of Noonan syndrome make tracheal intubation potentially risky.[168] Nevertheless, odontoid hypoplasia and atlanto-axial instability may result in cervical cord compression. Preoperative cervical spine evaluation is advisable.[169] Right ventricular function needs to be monitored closely because 30% to 50% of the patients with Noonan syndrome have pulmonary stenosis.[170] Regional anesthesia in Noonan patients may be technically challenging due to the prevalence of scoliosis. The spread of local anesthetic can be unpredictable.[169,171]

KDS features the dysmorphic facial and skeletal abnormalities similar to Noonan syndrome and congenital myopathy with proximal muscle weakness.[163] Sporadic cases have been reported in the literature.[172-181] The inheritance pattern of the disease is not clear. Elevated baseline CK appears in approximately one half of the KDS patients. A heterozygous A97G point mutation in exon 2 of the *RyR1*, causing a substitution of lysine for glutamine at amino acid residue 33 (Lys33Glu), was reported.[182] This substitution creates a major polarity change, from positive to negative, in a known hot spot for an MH causative mutation. Dowling and associates recently identified *RyR1* mutation in three out of the four patients with KDS, which supports the hypothesis of its genetic heterogeneity.[183] Given the strong evidence for MHS in KDS patients, MH triggering agents should be avoided for anesthesia on KDS patients.

BOX 35.1 Clinical Signs of Malignant Hyperthermia

Early Signs

Elevated end-tidal CO_2
Tachypnea and/or tachycardia
Masseter spasm if succinylcholine has been used
Generalized muscle rigidity
Mixed metabolic and respiratory acidosis
Profuse sweating
Mottling of skin
Cardiac arrhythmias
Unstable blood pressure

Late Signs

Hyperkalemia
Rapid increase of core body temperature
Elevated creatine phosphokinase levels
Gross myoglobinemia and myoglobinuria
Cardiac arrest
Disseminated intravascular coagulation

Diagnosis in the Operating Room and Postanesthesia Care Unit

As stated earlier, fulminant MH is rare, and early signs of clinical MH may be subtle (Box 35.1). These signs must be distinguished from other disorders with similar signs (Box 35.2).

When the diagnosis is obvious (i.e., fulminant MH or succinylcholine-induced rigidity with rapid metabolic changes), marked hypermetabolism and heat production occur, and there may be little time left for specific therapy to prevent death or irreversible morbidity. If the syndrome begins with slowly increasing end-tidal CO_2 (defined earlier), specific therapy can await a complete clinical workup before treatment. In general, MH is not expected to occur when no triggers are administered (see "Anesthesia for Susceptible Patients"). However, several confirmed fulminant nonanesthetic cases of MH that resulted in death have been reported (see "Nonanesthetic Malignant Hyperthermia").[148]

When volatile anesthetics or succinylcholine are used, MH should be suspected whenever there is an unexpected increase in end-tidal CO_2 ($ETCO_2$), undue tachycardia, tachypnea, arrhythmias, mottling of the skin, cyanosis, muscle rigidity, sweating, increased body temperature, or unstable blood pressure. If any of these occur, signs of increased metabolism, acidosis, or hyperkalemia must be sought. The most common cause for sudden $ETCO_2$ during general anesthesia and sedation is hypoventilation. Increased minute ventilation should be able to correct such a problem.

The diagnosis of MH can be supported by the analysis of arterial or venous blood gases which demonstrates a mixed respiratory and metabolic acidosis;[184] however, the respiratory component of acidosis may be predominate in the very early stage of the onset of fulminant MH. O_2 and CO_2 change more markedly in the central venous compartment than in arterial blood; therefore end-expired or venous CO_2 levels more accurately reflect whole-body stores. Venous CO_2, unless the blood drains an area of increased metabolic activity, should have PCO_2 levels of only about 5 mm Hg greater than that of expected or measured $PaCO_2$. In small children, particularly those without oral food or fluid for a prolonged period, the base deficit may be 5 mEq/L because of their smaller energy stores.

Any patient suspected of having an MH episode should be reported to the North American MH Registry via the adverse metabolic/muscular reaction to anesthesia (AMRA) report available from the website at http://anest.ufl.edu/namhr/namhr-report-forms/.

BOX 35.2 Conditions and Disorders that May Mimic Malignant Hyperthermia

Anaphylactic reaction
Alcohol therapy for limb arteriovenous malformation
Contrast dye injection
Cystinosis
Diabetic coma
Drug toxicity or abuse
Elevated end-tidal CO_2 due to laparoscopic operation
Environmental heat gain more than loss
Equipment malfunction with increased carbon dioxide
Exercise hyperthermia
Freeman-Sheldon syndrome
Generalized muscle rigidity
Heat stroke
Hyperthyroidism
Hyperkalemia
Hypokalemic periodic paralysis
Hypoventilation or low fresh gas flow
Increased $ETCO_2$ from laparoscopic surgery
Insufficient anesthesia and/or analgesia
Malignant neuroleptic syndrome
Muscular dystrophies (Duchenne and Becker)
Myoglobinuria
Myotonias
Osteogenesis imperfecta
Pheochromocytoma
Prader-Willi syndrome
Recreational drugs
Rhabdomyolysis
Sepsis
Serotonin syndrome
Stroke
Thyroid crisis
Ventilation problems
Wolf-Hirschhorn syndrome

TREATMENT

Acute management for MH can be summarized as follows:

1. Discontinue all triggering anesthetics, maintain intravenous agents, such as sedatives, opioids, and nondepolarizing muscular blockers as needed, and hyperventilate with 100% oxygen with a fresh flow to at least 10 L/min. With increased aerobic metabolism, normal ventilation must increase. However, CO_2 production is also increased because of neutralization of fixed acid by bicarbonate; hyperventilation removes this additional CO_2.
2. Administer dantrolene rapidly (2.5 mg/kg intravenously [IV] to a total dose of 10 mg/kg IV) every 5 to 10 minutes until the initial symptoms subside.

3. Administer bicarbonate (1-4 mEq/kg IV) to correct the metabolic acidosis with frequent monitoring of blood gases and pH.
4. Control fever by administering iced fluids, cooling the body surface, cooling body cavities with sterile iced fluids, and if necessary, using a heat exchanger with a pump oxygenator. Cooling should be halted at 38°C to prevent inadvertent hypothermia.
5. Monitor and treat arrhythmia. Advanced cardiac life support protocol may be applied.
6. Monitor and maintain urinary output to greater than 1 to 2 mL/kg/h and establish diuresis if urine output is inadequate. Administer bicarbonate to alkalinize urine to protect the kidney from myoglobinuria-induced renal failure.
7. Further therapy is guided by blood gases, electrolytes, CK, temperature, muscle tone, and urinary output. Hyperkalemia should be treated with bicarbonate, glucose, and insulin, typically 10 units of regular insulin and 50 mL of 50% dextrose for adult patients. The most effective way to lower serum potassium is reversal of MH by effective doses (ED) of dantrolene. In severe cases, calcium chloride or calcium gluconate may be used.
8. Recent data demonstrated that magnesium level could be a prerequisite for dantrolene efficacy in managing MH crisis.
9. Analyze coagulation studies (e.g., international normalized ratio [INR], platelet count, prothrombin time, fibrinogen, fibrin split, or degradation products).
10. Once the initial reaction is controlled, continued monitoring in the intensive care unit for 24 to 48 hours is usually recommended.

Adequate personnel support is critical to the successful management of such a crisis. Discontinuation of the trigger may be adequate therapy for acute MH if the onset is slow or if exposure was brief. Changing the breathing circuit and CO_2 absorbent can be time-consuming. However, application of activated charcoal filters may rapidly reduce the volatile anesthetic concentration to an acceptable level in less than2 minutes, if they are readily available.[185]

Dantrolene used to be packaged in 20-mg bottles with sodium hydroxide for a pH of 9.5 (otherwise it will not dissolve) and with 3 g of mannitol (converts the hypotonic solution to isotonic). The initial dose should be 2.5 mg/kg dantrolene reconstituted in sterile water and administered intravenously. Dantrolene *must* be reconstituted in sterile water rather than salt solutions or it will precipitate. It has been shown that prewarming of sterile water may expedite the solubilization of dantrolene compared to water in ambient temperature.[186] In 2009, a newer, rapid soluble lyophilized powder form of dantrolene became available for intravenous use. It reconstitutes in less than a minute which is much faster than the older version.[187] The higher dosing capacity, 250 mg per vial, of the newer version of dantrolene also reduces the storage space with a similar recommended shelf life as the older versions.

In awake, healthy volunteers, the maximum twitch depression occurs at a dantrolene dose of 2.4 mg/kg.[188] Therefore it is not surprising that at therapeutic concentrations, dantrolene may prolong the need for intubation and assisted ventilation. Brandom and associates reviewed the complications associated with the administration of dantrolene from 1987 to 2006 using the dataset in the NAMHR via the AMRA reports and found that the most frequent complications of dantrolene were muscle weakness (21.7%), phlebitis (9%), gastrointestinal upset (4.1%), respiratory failure (3.8%), hyperkalemia (3.3%), and excessive secretions (8.2%).[189] Given its high pH, it is advisable to administer dantrolene through a large bore IV line. It has been demonstrated that dantrolene interferes with EC coupling of murine intestinal smooth muscle cells,[190] rat gastric fundus, and colon,[191] which in part explains its gastrointestinal side effect. Caution should be used when ondansetron is to be used in this setting. As a serotonin antagonist, ondansetron may increase serotonin at the 5-HT_{2A} receptor in the presynaptic space. In MHS individuals, agonism of 5-HT_{2A} receptor may produce a deranged response, precipitating MH.[192]

The clinical course will determine further therapy and studies. Dantrolene should probably be repeated at least every 10 to 15 hours, since it has a half-life of at least 10 hours in children and adults.[188,193] The total dose of dantrolene that can be used is up to 30 mg/kg in some cases. Recrudescence of MH can approach 50%, usually within 6.5 hours.[194,195] When indicated, calcium and cardiac glycosides may be used safely. They can be lifesaving during persistent hyperkalemia. Slow voltage-gated calcium channel blockers do not increase porcine survival.[196,197] Instead, a recent study by Migita demonstrated that calcium channel blockers, including dihydropyridine (i.e., nifedipine), phenylalkylamine (i.e., verapamil), and benzothiazepine (i.e., diltiazem), led to increased $[Ca^{2+}]_i$ in human skeletal muscle cells. Interestingly, the potency of such calcium release is correlated with the number of binding sites on DHPR (i.e., nifedipine > verapamil > diltiazem).[198] Clinical doses of dantrolene were only able to attenuate 20% of the nifedipine-induced $[Ca^{2+}]_i$ surge. [198] Current recommendations of MHAUS discourage the use of calcium channel blockers in the presence of dantrolene because they can worsen the hyperkalemia resulting in cardiac arrest. Although administration of magnesium sulfate could not prevent the development of MH and did not influence the clinical course in succinylcholine-induced MH,[199] recent data suggested that dantrolene might require magnesium to arrest the course of MH triggered by halothane.[200] Permanent neurologic sequelae, such as coma or paralysis, may occur in advanced cases, probably because of inadequate cerebral oxygenation and perfusion for the increased metabolism and because of the fever, acidosis, hypo-osmolality with fluid shifts, and potassium release.

For MH cases diagnosed in the ambulatory surgical centers, guidelines have been recently proposed for the transferring of care to receiving hospital facilities.[201] Although it is preferable that immediate treatment and stabilization of the patient be achieved onsite, several factors need to be considered before implementation of a transfer plan, which include capabilities of the available professionals at the initial treatment and receiving facilities, clinical best interests of patients, and capabilities of the transfer team.[202] The validity of stocking dantrolene in ambulatory surgery centers was confirmed with a cost-effectiveness analysis.[203]

Anesthesia for Susceptible Patients

Safe anesthetics consist of nitrous oxide, barbiturates, etomidate, propofol, opiates, tranquilizers, and nondepolarizing muscle relaxants. Potent volatile anesthetics and succinylcholine must be avoided, even in the presence of dantrolene. There are anecdotal reports that some human patients have experienced a hypermetabolic state despite these precautions, but they have always responded favorably to the administration of intravenous dantrolene. Preoperative dantrolene is never needed because the use of nontriggering agents is almost always associated with uneventful anesthesia. Regional anesthesia is safe and may be preferred. Amide anesthetics such as lidocaine were once considered dangerous in susceptible patients because they were thought to induce or worsen muscle contractures in vitro as a result of their effect of increasing calcium efflux from the SR. Porcine and human studies have consistently demonstrated the lack of danger of amide anesthetics.

Before being used for MHS patients, anesthetic machines may be "cleansed" of potent volatile agents by disconnecting or removing the vaporizers from the anesthesia workstation, renewing the CO_2 absorbent, using a new, disposable breathing circuit, and, if possible, a fresh gas hose. If there is no dedicated machine for MHS patients, flushing the anesthesia workstation to less than5 parts per million (ppm) of the volatile anesthetic agents concentration is generally accepted.[204] It may take 10 to 104 min with different machines.[185,205-214] This preparation process also should be directed based on the halogenated volatile agents that have been used. Jones and colleagues demonstrated that desflurane required longer purge time than sevoflurane on both the Datex-Ohmeda Aestiva and Aisys machines.[213] Application of activated charcoal filters have been shown to successfully accelerate the process of cleansing.[185,215-217] Such filters should be placed on both the inspiratory and expiratory limbs of the anesthesia machine with replacement of a new set every 60 minutes on patients who are exhaling volatile anesthetics.[185] MHAUS recommends flushing and preparing the anesthesia workstation according to the manufacturer's recommendations or published studies.[218] During the case, lowering the fresh gas rate after the washout period may allow the concentration of volatile anesthetic agents to reaccumulate.[209] Fresh gas flow should be kept to at least 10 L/min to avoid this rebound.

It is important to be aware that the National Institute for Occupational Safety and Health issued "Criteria for a Recommended Standard- Occupational Exposure to Waste Anesthetic Gases (WAGs) and Vapors."[219] No worker is exposed to halogenated anesthetic agents at concentrations greater than 2 ppm when used alone or greater than 0.5 ppm when used in combination with nitrous oxide over a sampling period not to exceed 1 hour. Anesthetic gas machines, non-rebreathing systems, and T-tube devices shall have an effective scavenging device that collects all WAGs. Occupational Safety and Health Administration also has guidelines for workplace exposures.[220]

The anesthesiologist should confidently discuss anesthetic care with MHS patients and assure them that all will be done to avoid difficulties with MH and that the appropriate drugs, knowledge, and skills are immediately at hand if any problems occur. Many of these patients have undergone procedures uneventfully, such as dental analgesia and obstetric anesthesia, before the diagnosis of susceptibility was made. The patient can enter the therapeutic environment in a reassured, relaxed, and comfortable state. Outpatient procedures are feasible in most environments; the time of discharge depends on the usual outpatient criteria.

Any facility using MH triggers on an inpatient or outpatient basis should have dantrolene available immediately. The current recommendation by MHAUS to stock 36 vials of 20 mg dantrolene Dantrium/Revonto is based on dantrolene needed to treat an MH crisis on a 70-kg patient.[187] FDA approved the Ryanodex in 2014. Administration of three vials of 250 mg Ryanodex injectable suspension is the alternative preparation plan.

EVALUATION OF SUSCEPTIBILITY

Evaluation of susceptibility includes a history and physical examination to detect any subclinical abnormality. A genealogy with specific information about anesthetic exposure and agents can estimate the likelihood of exposure to triggering agents. Blood CK values, when determined in a resting, fasting state without recent trauma, reflect muscle membrane stability. When the CK level is elevated in a close relative of a person with known MHS, the relative may be considered to have MHS without contracture testing. If the CK level is normal on several occasions, there is no predictive value, and contracture studies are necessary. The patient must travel to the test center for a surgical biopsy to ensure viability and accurate results. Muscle biopsy contracture studies, performed at about 30 centers around the world, involve exposure of the muscle biopsy sample to halothane, caffeine, and, in the North American test, to halothane plus caffeine.[128] Sensitivity to 4-chloro-*m*-cresol or ryanodine have also been used by some centers.[52] It is also important to note that contracture responses are sometimes positive in patients with myopathies that bear no direct relationship to MH and therefore may not indicate susceptibility. Dantrolene must be avoided before biopsy because it masks the response to contracture-producing drugs. After a patient is diagnosed as being MHS, DNA testing for mutations should follow. When a mutation is detected, other relatives with that mutation should be considered to be MHS without the need for an invasive contracture test, and they need not travel to a testing center (see Genetics).

MHS patients and all patients who are not biopsy tested, but who present with a clinical picture that suggests a high probability for MHS, should be given advice. Precautions are necessary in regard to general anesthesia, and triggers include all potent volatile agents and succinylcholine. Awake episodes are uncommon, and if not experienced before diagnosis, they are an unlikely problem. The true predictive value (i.e., percentage of positive results that are true positives) or efficiency (i.e., percentage of all results that are true, whether positive or negative) of contracture testing in determining susceptibility in the general population cannot be estimated because of the selection process that has been used to date for testing (i.e., limited to those with anesthesia reactions who do not have any other muscle disease pathology). False-positive results from cautious interpretation or decreased specificity are masked because the patient will never be exposed to triggering agents. A promising innovative in vivo human application involves physiologically based microdialysis infusion of caffeine or halothane into muscle of MHS patients to trigger exaggerated localized changes in acid-base balance.[221-225] White blood cells express RyR1-MHS and provide a substrate for a less invasive analysis for susceptibility but have the limitation that not all causative mutations are expressed in the white blood cells.[226-230] Nuclear magnetic resonance has promise,[231,232] but to date it has been difficult to standardize a stress, such as forearm ischemia, that can differentiate susceptibles from normals.

For anesthesia assessment of the non-MHS pregnant patient carrying a potential MHS fetus, the parturient should be treated as MHS until the fetus is delivered.[233-235] For emergencies in such patients, the use of succinylcholine, although little of the drug crosses the placenta, is controversial.[236]

Multiple Sclerosis

Multiple sclerosis (MS) is an autoimmune disorder characterized by T-cell–mediated autoantibodies against myelin and a subsequent inflammatory response within the central nervous system (CNS: brain and spinal cord), where it primarily affects the optic nerve, the corticospinal tract, or posterior columns. Thus MS is a disorder of the myelinated part of the axon that leads to secondary nerve conduction failure. It is characterized by sensitization of the peripheral leukocytes to the myelin antigen and a subsequent inflammatory response, monocytic and lymphocytic perivascular cuffing, and glial scars with plaque formation within the central nervous system, especially in the periventricular white matter. The disease affects mainly women, primarily between 20 and 40 or 45 and 60 years of age. Although the etiology is unknown, it has been speculated that MS is caused by environmental factors combined with a genetic predisposition. Naturally, researchers have focused on identifying key events and the genetic origin of the disorder to provide diagnostic and possibly also therapeutic tools for the management of MS patients.

Its clinical course is characterized by exacerbations and remissions in most patients, but continuous neurological deterioration has been reported in up to 10% of cases (primary progressive MS). Patients with MS frequently report paresthesias, muscle weakness, and sensory disturbances. Acute symptoms, which are related to the site and extent of sclerosing CNS plaques, commonly include visual disturbances (diplopia, blurring, and field cuts), sensory abnormalities with numbness and paresthesia, pain, and electric shock sensation that radiates down the spine and into the limbs upon flexion of the neck (Lhermitte sign). Cranial nerve dysfunction, ataxia, and bladder and bowel disturbances are also common. Typically, there is a localized or, late in the course of disease, generalized muscle weakness with the legs affected more than the arms. Chronic symptoms can also include spastic paraparesis, appendicular tremor, psychiatric disturbances such as depression or euphoria (la belle indifference), and dementia. In severe cases, respiration may be involved with the development of hypoxemia. As a rule, symptoms are closely related to the site affected within the CNS, and the number of symptoms is related to the extent of sclerosing CNS plaques. Notably, MS can be associated with impaired autonomic function, and hence an increased risk for exaggerated hemodynamic response to anesthetic induction agents, vasodilators, and sympathomimetic drugs.[237]

Diagnosing MS after a single, acute remitting clinically isolated syndrome is discouraged, whereas repeated attacks with increased CSF IgG and multifocal MRI abnormalities are strongly supportive of the diagnosis.[238] Acute attacks are treated with various combinations of immunosuppression modalities including glucocorticoids or plasma exchange therapy, which have been shown to increase the rate of recovery but not the overall level of recovered function. Disease progression can, nevertheless, be modified with a novel humanized CD20 monoclonal antibody (ocrelizumab) in patients with primary-progressive or relapsing-remitting forms of MS. Other immunomodulatory treatment options include interferon β1a or glatiramer acetate (a mixture of polypeptides synthesized to mimic myelin basic protein) in individuals with the relapsing-remitting MS, fingolimod, teriflunomide, or natalizumab, and the antineoplastic agent mitoxantrone. Teriflunomide is associated with hepatic injury, while mitoxantrone can be associated with cardiomyopathy. These patients may also receive treatments aimed at reducing spasticity (baclofen and benzodiazepines), as well as anticonvulsants or propranolol for tremor, oxybutynin and propantheline for bladder spasticity, and SSRIs or other antidepressive agents for mood disorders.

ANESTHETIC CONSIDERATIONS

It has been speculated that general anesthesia and surgery may increase the risk for aggravation of MS.[239] Presently, there is no general consensus on this matter, and patients should therefore be informed of the potential for aggravated symptoms in the postoperative period. In general, preoperative chronic immunosuppressive medication should be continued during the perioperative period. Patients with MS are sensitive to physical (pain, fever, infection) and emotional stress, which makes it more likely that symptoms will be intensified in the perioperative period. Increased body temperature is often cited as an offending mechanism, possibly by causing a complete block of conduction in demyelinated nerves. Body temperature should therefore be closely monitored and controlled during the perioperative period. Great care must be exercised to minimize changes in fluid homeostasis, and central hemodynamics (preload, afterload) and to maintain respiration. Although intravenous induction agents and volatile anesthetics have been used safely, it is wise to avoid administering depolarizing neuromuscular blocking drugs to MS patients. MS-induced denervation, or misuse myopathy, may lead to a risk for succinylcholine-induced hyperkalemia, which can result in fatal cardiac arrhythmias. Nondepolarizing neuromuscular blockers are safe to use but should be dosed cautiously as both prolonged responses (increased sensitivity in patients with preexisting muscle weakness) and resistance to these NMBAs have

BOX 35.3 **Perioperative Considerations for Patients with Multiple Sclerosis**

1. Thoroughly inform the patient and family of the natural course of MS, and the risk for perioperative worsening of symptoms
2. Continue preoperative immunosuppressive therapy
3. Type of general anesthetics is unlikely to affect the course of disease
4. Minimize perioperative changes in fluid homeostasis and hemodynamics
5. Monitor body temperature closely, avoid hyperthermia
6. It is reasonable to avoid depolarizing neuromuscular blocking agents (NMBAs)
7. Nondepolarizing NMBAs can be used, but should be dosed cautiously with monitoring of the neuromuscular transmission
8. Epidural anesthesia has been used successfully, but spinal anesthesia is usually not recommended
9. Consider extended postoperative care in a monitored setting if patient has severe preoperative weakness or respiratory compromise

been reported. The use of rocuronium with sugammadex to ensure full reversal has been suggested as a safe alternative.[240] It is speculated that the demyelination associated with MS renders the spinal cord susceptible to the neurotoxic effects of the local anesthetics. Epidural application of low concentrations of local anesthetics has, nevertheless, been successfully used in MS patients.[239] Spinal anesthesia, on the other hand, has been implicated in postoperative exacerbations of symptoms in MS. As the blood–brain barrier may also be damaged by demyelination, spinal anesthesia is usually not recommended for these patients. A recent metaanalysis of 37 reports found that the MS symptoms were worsened in 10 of 231 patients, but despite the association no clear cause-effect relationship could be identified.[241] Notably, postpartum worsening of MS symptoms is noted in 20% of females. The need for postoperative care is dependent on the preoperative symptoms, type of surgery, and status of the patient at the end of the surgical procedure. In this context, MS patients with severe weakness and respiratory distress, including pharyngeal dysfunction, may need extended postoperative care, such as noninvasive respiratory support and intense physiotherapy, to avoid further impairment of their pulmonary function (Box 35.3).

Motor Neuron Disorders

Motor neuron disorders involve either the upper or the lower motor neurons of the cerebral cortex, brainstem, and spinal cord. Some forms are mixed, whereas others have predominately upper or lower motor neuron involvement. Amyotrophic lateral sclerosis (ALS, also known as Lou Gehrig's disease) is the most common disease within this group and involves both upper and lower motor neurons. Other examples of motor neuron disease are Kennedy disease (spinobulbar muscular atrophy), Friedreich ataxia (mixed upper and lower motor neurons), and spinal muscular atrophy (lower motor neurons).

ALS is characterized by degeneration of the anterior horn α-motoneurons in the spinal cord and brainstem motor nuclei, as well as the primary descending upper motor neurons of the corticospinal tract. Degenerative loss of these neurons leads to progressive muscle weakness, muscle atrophy, and loss of neuronal mass in these locations. Patients present with gradually spreading focal weakness and muscle atrophy (typically of the hands), spasticity, and hyperreflexia of lower extremities. Dysarthria and dysphagia, tongue atrophy, and fasciculations may also occur. Progressive weakness can lead to respiratory failure and death. Sensory functions, including intellectual capacity and cognition, as well as bowel and bladder function, are not usually affected in ALS.

ALS has an incidence of about 2 in 100,000, and onset of the disease usually takes place around 40 to 50 years of age, with males more often affected than females. Most cases are sporadic, but rare familial forms (autosomal dominant and recessive forms) do exist. The underlying mechanism or mechanisms for this selective and progressive motor neuronal death are thus far unclear, but it has recently been suggested that superoxide dismutase (SOD) mutations may have a key role in the increased formation of free radicals seen in subsets of patients. SOD is an important antioxidant and its mutation can lead to decreased clearance of free radicals, increased oxidative stress, and mitochondrial dysfunction. Most familial forms are associated with the mutation of C9ORF72 on 9p21, TDP43, FUS, and VCP genes. The diagnosis is made by electrophysiology (electromyography [EMG] and electroneurography), neurologic examination, MRI imaging, and CSF analysis, which demonstrates early spastic weakness of the upper and lower extremities, typical subcutaneous muscle fasciculations, and bulbar involvement affecting pharyngeal function, speech, and the facial muscles. No curative treatment is currently available, and patients are therefore treated symptomatically. Riluzole, a glutamate release inhibitor, may provide neuroprotection and extend survival in these patients.[242] More recently, the antioxidant edaravone was shown to reduce the decline in daily functioning associated with ALS.[243] Patients may also receive spasmolytic and analgesic agents. Those with advanced disease will ultimately require tracheostomy and gastrostomy surgeries and other supportive treatments including mechanical ventilation.

ANESTHETIC CONSIDERATIONS

Bulbar involvement in combination with respiratory muscle weakness leads to a risk for aspiration and pulmonary complications. Notably, these patients may have increased sensitivity to the respiratory depressant effects of sedatives and hypnotics. There are reports of sympathetic hyperreactivity and autonomic failure.[244] Sympathetic hyperreactivity and autonomic dysfunction, often manifested as orthostatic hypotension and resting tachycardia but also significant hypotension or even pulseless electrical activity upon anesthesia induction, have been reported,[245] and should be considered during the perioperative management of these patients.[244] Succinylcholine should be avoided because of the risk for hyperkalemia as a result of denervation and immobilization. Nondepolarizing NMBA may cause prolonged and pronounced neuromuscular blockade and hence should be used with great caution.[246] General anesthesia may be associated with exaggerated ventilatory depression. Regional anesthesia is also often avoided

BOX 35.4 **Perioperative Considerations for Patients with Amyotrophic Lateral Sclerosis**

1. Exaggerated respiratory depression and sensitivity to sedatives and hypnotics
2. Higher risk for aspiration and pulmonary complications
3. Autonomic dysfunction with risk for hemodynamic instability
4. Avoid depolarizing neuromuscular blocking agents (NMBAs) (risk for hyperkalemia); nondepolarizing NMBAs may cause prolonged and profound neuromuscular blockade
5. General and epidural anesthesia have been successfully administered; spinal anesthesia is often avoided

for fear of exacerbating disease symptoms. Both general and epidural anesthesia have, however, been successfully administered to these patients without reported complications (Box 35.4).

Guillain-Barré Syndrome

Guillain-Barré syndrome or acute inflammatory demyelinating polyradiculopathy is an acute inflammatory polyneuritis that is triggered by humoral and cell-mediated autoimmune response to a sensitizing event. Although the etiology is unknown, in many cases a timely association with a viral (influenza-like) or bacterial infection or even lymphomatous disease can be demonstrated.[247] It typically presents as an ascending paralysis characterized by symmetric weakness that can vary from mild difficulty with walking to nearly complete paralysis of all extremities, facial, respiratory, and bulbar muscles. Mild variants can present with ataxia, ophthalmoplegia, or hyporeflexia without significant appendicular weakness. Fulminant cases can present with severe ascending weakness leading to complete tetraplegia, and paralysis of cranial nerves and phrenic and intercostal nerves with facial and respiratory muscle weakness necessitating tracheostomy and ventilatory support.[248] Importantly, patients may also have autonomic involvement that could lead to hemodynamic instability and arrhythmias with risk for sudden circulatory collapse and fatal cardiac.

The diagnosis is made after careful neurologic examination such as areflexia and progressive motor weakness, clinical and electrophysiological studies,[249] and CSF analysis. CSF analysis may show a typical increase in CSF protein in combination with a normal cell count, which is a classic sign of the disease. Electromyogram (EMG) and nerve conduction studies may be normal in the early acute period, but characteristic segmental demyelination and reduction of conduction velocity and dispersion or absence of F-waves are usually seen within 1 to 2 weeks.

Management is primarily supportive and includes nutritional support, respiratory support, and measures to prevent aspiration. Early plasma exchange, typically five exchanges with 5% albumin repletion, may mitigate the course but is contraindicated in setting of hemodynamic instability, marked dysautonomia, and active bleeding.[250] Intravenous immunoglobulin (IVIG) is typically administered in the setting of dysautonomia, or if plasmapheresis and exchange transfusion are contraindicated.

BOX 35.5 **Perioperative Considerations for Patients with Acute Inflammatory Demyelinating Polyradiculopathy**

1. Autonomic dysfunction may be associated with hemodynamic instability and an exaggerated response to anesthesia induction agents, or to stimulating interventions such as laryngoscopy
2. Depolarizing neuromuscular blocking agents (NMBAs) should be avoided due to an upregulation of the acetylcholine receptors and risk for hyperkalemic response
3. Nondepolarizing NMBAs can be used but are commonly also avoided because of the risk for prolonged weakness
4. The use of regional anesthesia is controversial and may be associated with worsening symptoms

ANESTHETIC CONSIDERATIONS

Cranial nerve paralysis and autonomic dysfunction predispose these patients to an increased risk for aspiration. Aspiration precautions, including decompression of the stomach, should therefore be considered before the induction of anesthesia. Absence of compensatory cardiovascular responses may be associated with exaggerated hypotension at anesthesia induction or in response to hypovolemia. Conversely, laryngoscopy or noxious stimuli can be associated with an exaggerated increase in blood pressure. The hemodynamic instability is typically short-lived and self-limited, but small doses of short-acting and titratable vasoactive medications may be required.[251] Careful hemodynamic monitoring is essential and continuous monitoring of the blood pressure with an arterial catheter is often considered. These patients may also exhibit abnormal responses to NMBA; succinylcholine should not be used because of the risk of hyperkalemia. Nondepolarizing muscle relaxants are not contraindicated but should be avoided as a result of the increased sensitivity and risk for prolonged muscle weakness in the postoperative period. The risk for autonomic dysfunction, respiratory failure, and aspiration may require assisted or mechanical ventilation, even in the postoperative period. If these agents are used, the neuromuscular transmission should be closely monitored with a nerve stimulator as both resistance and sensitivity to these agents have been reported. Great care should be taken to maintain circulatory stability, including adequate cardiac preload and afterload. Careful hemodynamic monitoring is therefore essential in these patients.

Regional anesthesia is employed by some practitioners[252] but its use remains controversial as it has been reported to cause worsening of neurological symptoms.[253] General anesthesia can be used; however, the combination of general anesthesia and epidural anesthesia is more controversial (Box 35.5).[254]

CRITICAL ILLNESS POLYNEUROPATHY AND CRITICAL ILLNESS MYOPATHY

Despite earlier reports of a rapid development of weakness, muscle atrophy, and polyneuropathy in critically ill patients, it was not until the 1987 report by Bolton and associates that the characteristic widespread axonal degeneration of motor and sensory fibers and the extensive denervation atrophy of limb and respiratory muscle associated with this polyneuropathy were clearly identified.[255] Although the

BOX 35.6 Perioperative Considerations for Patients with Critical Illness Polyneuropathy

1. Particular attention should be made to protect peripheral nerves, in particular the ulnar and peroneal nerves, during positioning of these patients
2. Monitor and correct electrolyte and glucose abnormalities
3. Steroids have been implicated in the pathophysiology of the disease and should therefore be avoided
4. Neuromuscular blocking agents are best avoided altogether, but if needed only nondepolarizing agents should be considered

true incidence of critical illness polyneuropathy (CIP) is difficult to determine, critical illness neuropathy and myopathy are believed to affect up to 50% of all patients remaining in the intensive care unit for more than 2 weeks.[256] It is typically manifested as profound symmetric limb weakness, with reduced or absent tendon reflexes and diaphragmatic and intercostal weakness. It affects the lower extremities to a greater extent than upper extremities, and distal muscle groups more severely than the proximal. The autonomic function is not affected and the extraocular eye movements remain intact. In CIP, there is no evidence of neuromuscular junction disorder and the electromyography and nerve conduction study findings are consistent with axonal motor and sensory polyneuropathy, with amplitude reduction of motor and sensory action potentials, and slowed conduction velocities. Serum CK levels are usually normal. Conversely, a sensory nerve action potential is often normal in critical illness myopathy but compound muscle action potentials are diminished and electromyography is consistent with myopathy. Serum CK levels may be elevated. No specific treatments are currently available, and management is supportive with aggressive and early rehabilitation. Use of sedation, paralytics, and corticosteroids should be limited,[257] and aggressive control of hyperglycemia has been suggested to reduce the incidence of CIP by 44%.[258]

ANESTHETIC CONSIDERATIONS

Anesthetic considerations in CIP patients are similar to those with other acquired neuropathies (see above), and include protection of nerve compression sites, particularly the ulnar and peroneal nerves. Prolonged immobility in critically ill patients is associated with a relative increase in immature acetylcholine receptors that can lead to an insensitivity to nondepolarizing NMBA.[259] Conversely, the sensitivity to depolarizing neuromuscular blockers is increased, with a risk for increased potassium efflux after succinylcholine administration (Box 35.6).[260]

Hereditary Motor-Sensory Neuropathies, including Charcot-Marie-Tooth Disease

Hereditary motor-sensory neuropathies include a spectrum of peripheral neurologic disorders, among which Charcot-Marie-Tooth (CMT) disease is often listed. They are caused by a specific mutation in one of several myelin genes that result in defects in myelin structure, maintenance, and formation. Hereditary motor-sensory neuropathies have been classified into seven types and multiple subtypes according to the age at onset, mode of inheritance, predominately involved muscle groups, and genotypes.[261,262] CMT types 1 and 2 are the most common hereditary peripheral neuropathies, with an estimated prevalence of 40 per 100,000.[262] Patients with CMT disease typically experience slow and progressive distal muscle weakness and wasting. Damage to sensory axons may also lead to sensory loss resulting in frequent tripping and falls. Neuropathic pain may develop in some patients. CMT patients usually have normal life expectancy. CMT type 3, also known as Dejerine-Sottas disease, is a very severe condition with an early onset of hypotonia during infancy. Nerve conduction velocity is typically significantly reduced to less than 10 ms.[262] The genetic inheritance pattern for CMT disease is heterogeneous.

ANESTHETIC CONSIDERATIONS

The anesthesia experience in patients with CMT disease is limited because of the small number of cases. Major considerations include the use of hypnotic agents, muscle relaxants, volatile agents, and neuraxial techniques. CMT type 1 patients have been reported to have significantly increased sensitivity to thiopental at induction that correlates with the severity of both motor and sensory defects. However, total intravenous anesthesia (TIVA) has been performed successfully in a number of cases without any reported problems.[263-265]

Because of the reduced number of acetylcholine receptors, sensitivity to nondepolarizing muscle relaxants is elevated and the response to succinylcholine is also reduced.[266] Although succinylcholine has been used without adverse effect,[267,268] the risk of an exaggerated hyperkalemic response may be sufficient to preclude it from being used in patients with suspected muscular denervation.[268] Prolonged neuromuscular blockade with vecuronium has been reported.[269] As a result of the large variety of disabilities in this patient group, careful baseline assessment of neuromuscular status should be conducted before the use of nondepolarizing neuromuscular relaxants. Normal response to atracurium and mivacurium has been demonstrated.[270,271] Both TIVA and volatile anesthetics have been used safely in CMT patients in a series of cases.[267] Neuraxial techniques for obstetric procedures have been reported to generally be successful in CMT patients.[272-275] However, the use of regional anesthesia can be controversial given that the possible complications may exacerbate the neurologic symptoms.[276] Similar medicolegal concerns may apply to the surgical and anesthesia positioning of CMT patients because of the sensory deficits and limb deformities.

Duchenne Muscular Dystrophy and Becker Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is the most common and severe type of muscular dystrophy, with an incidence of 1 per 3500 live male births[277] and a total male prevalence of about 50 to 60 × 10^{-6}.[278] Becker muscular dystrophy (BMD) is relatively rare and has an incidence of about 1 in

18,000 live male births and a prevalence of 23.8×10^{-6}.[278] Both DMD and BMD are X-linked recessive diseases. The defect is located on the short arm of the X chromosome at the Xp21 region, which contains the gene for the large protein Dp427, also known as dystrophin. The dystrophin gene is 2500 kilobases long with more than 70 exons.[278] Dystrophin is distributed not only in skeletal, cardiac, and smooth muscle but also in the brain.[279] Because of the large size of the dystrophin gene, spontaneous new mutations are common and account for a third of new cases.[280]

The most common form of mutation is a deletion within the gene (65%-70% of cases of DMD and >80% of BMD). Duplication and point mutations are responsible for the rest. It also appears that there are "hot spots" within the first 20 exons and in the central region of the gene (exons 45-55) where deletion and duplication are likely to occur.[278] Female cases of DMD have been reported with the 45,X and 46,XX karyotypes. The disease mechanism for the female 46,XX karyotype was thought to be preferential loss of the paternal X chromosome by postzygotic nondisjunction and manifestation of the DMD gene from the maternal X chromosome in muscle cells.[281] BMD is usually milder in severity than DMD because disruption of the translation process occurs in the relatively distal part of the gene, which leads to a reduced amount of truncated dystrophin protein.[278,282]

Dystrophin, along with dystrophin-associated glycoproteins (DAGs), is involved in sarcolemmal stability. Dystrophin is responsible for maintenance of muscle membrane integrity despite the fact that it accounts for only approximately 0.002% of the protein in striated muscle.[283] Dystrophin aggregates and links to actin (at its N terminus) and the DAG complex (at its C terminus) to form a stable structure that interacts with laminin in the extracellular matrix (Fig. 35.4). Lack or dysfunction of dystrophin leads to cellular and membrane instability, with progressive leakage of intracellular components and elevation of creatine phosphokinase (CPK) levels. Eventually, damaged muscle cell units are invaded by macrophages and destroyed. Current study suggests that cytotoxic T cells are probably the culprit. Consequently, clinical pseudohypertrophy of the muscle occurs when the dead muscle shells are replaced by fibrofatty infiltrates. Loss of muscle units accounts for the weakness and contracture.[279]

Both DMD and BMD are characterized by progressive weakness and wasting of predominantly the proximal musculature. Pseudohypertrophy of the calves and other muscle groups is common. As the more severe of the two diseases, DMD tends to be symptomatic early in life. Seventy-four percent of children with DMD were found to manifest the disease by 4 years of age.[277] DMD patients do not usually begin to walk until they are about 18 months of age or later.

The initial clinical findings include a waddling gait, frequent falling, and difficulty climbing stairs because of proximal muscle weakness in the pelvic girdle. The classic Gower maneuver describes rising from a sitting to a standing position with the help of both arms. Patients may also show weakness in the shoulder girdle and trunk erectors that leads to thoracolumbar scoliosis. The earlier the onset of disease, the more rapid the disease will take its course. In most cases, children with DMD are unable to walk by the age of 9 to 11. Proximal deep tendon reflexes in the upper extremities and patella may also disappear despite the lack of denervation.[282] Nevertheless, the Achilles tendon reflex remains intact even in later stages of the disease. Sixty percent of patients will have pseudohypertrophy of the calves, and thirty percent will have macroglossia. Some may also suffer from pain in the calves with activity.

The intellectual impairment that can be associated with the disease was thought to be related to limitation of educational opportunities. However, with equalization of educational opportunities, psychometric studies have revealed a significantly lower average intelligence quotient in DMD

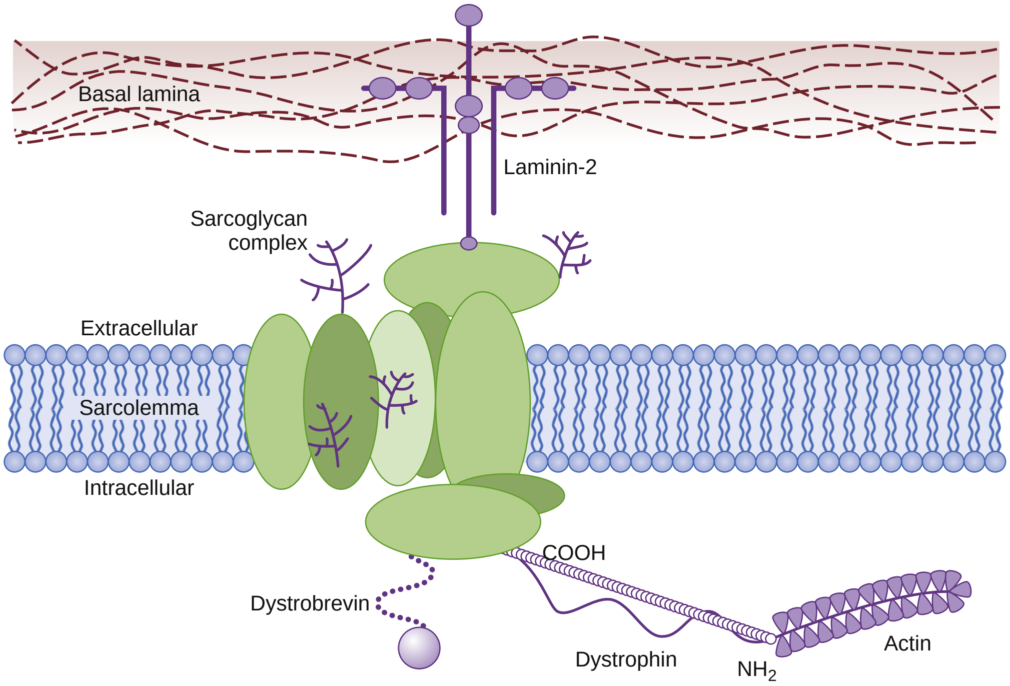

Fig. 35.4 Diagram of the cell–surface and cytoskeleton protein complex.

patients than in healthy groups.[284] This implies a possible effect of dysfunctional dystrophin in the brain on learning.

Death in patients with DMD is commonly due to cardiopulmonary compromise in their 30s.[277] BMD is a mild form of DMD. The mutation that causes BMD produces dystrophin that retains partial function. The onset of symptoms occurs in the second or third decade of life. As a result, the life span of BMD patients can reach the early 40s. Pneumonia is the most common cause of death (Fig. 35.5).[282]

The heart is also affected to various degrees, depending on the stage of the disease and the type of mutation. Cardiac degeneration is due to replacement of myocardium by connective tissue or fat, which leads to dilated cardiomyopathy.[285] Cardiac involvement starts early in the course of the disease, although clinical signs are not usually obvious in the early stage. No correlation has been established between the severity of cardiac disease and the severity of skeletal disease. Studies of necropsy have shown that the cardiomyopathy in DMD involves the posterobasal and contiguous lateral left ventricular walls as initial and primary sites of myocardial dystrophy in the absence of small vessel coronary artery disease in these areas.[286] Typical initial manifestations on the electrocardiogram (ECG) in DMD and BMD are sinus tachycardia, tall R waves in the right precordial leads, prominent left precordial Q waves, increased QT dispersion, and inverted T waves from scarring of the posterobasal portion of the left ventricle. Initially, the echocardiography is normal or shows regional wall motion abnormalities in areas of fibrosis. With the spreading of fibrosis, left ventricular dysfunction can be seen and ventricular arrhythmias frequently occur as well. In the final stages of the disease, systolic dysfunction may lead to heart failure and sudden death. Subclinical or clinical cardiac involvement is present in about 90% of DMD/BMD patients, but it is the cause of death in only 20% of DMD and 50% of BMD patients. Angiotensin-converting enzyme inhibitors are recommended in early stages of the disease, and β-blockers may be an additional option if indicated.[285]

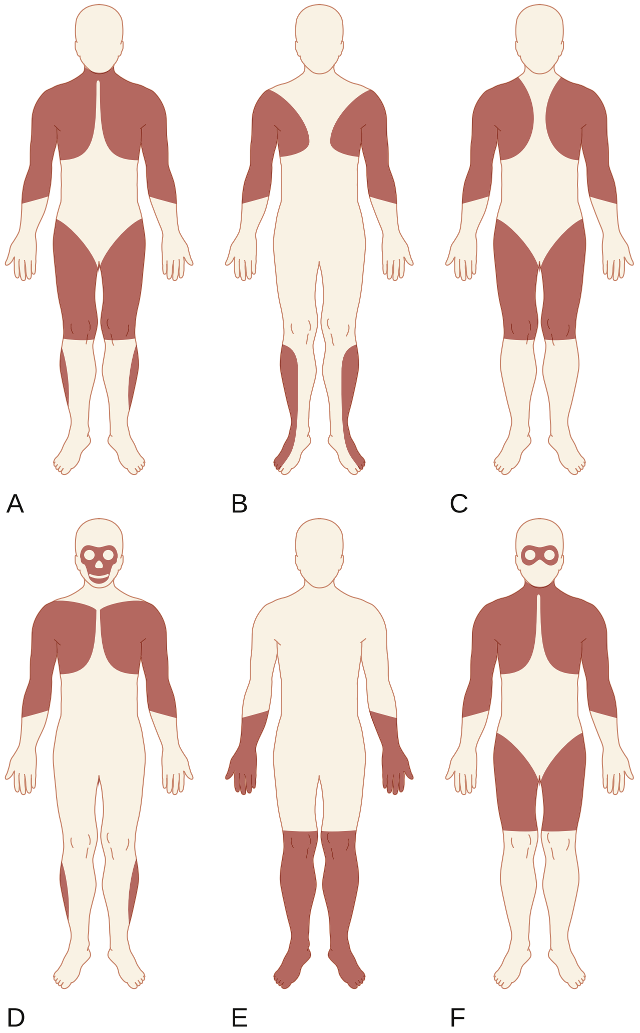

Fig. 35.5 Distribution of predominant muscle weakness in different types of dystrophy: (A) Duchenne type and Becker type; (B) Emery-Dreifuss; (C) limb girdle; (D) facioscapulohumeral; (E) distal; and (F) oculopharyngeal. (Redrawn from Emery AE. The muscular dystrophies. *BMJ* 1998;317:991–995.)

Pulmonary insufficiency is a leading cause of morbidity and mortality in DMD.[287] Usually, expiratory muscle function is affected first, because of the early onset of abdominal muscle weakness. By contrast, inspiratory muscle function is relatively preserved in the first decade, implying sparing of the diaphragm.[288] Vital capacity (VC) increases in the first decade because of overall body growth, plateaus in early adolescence, and then declines dramatically as the diaphragmatic weakness progresses.[288] Other measured lung volumes such as inspiratory reserve volume and total lung capacity (TLC) follow the same pattern. A disproportionate loss of VC and TLC relative to the respiratory muscle dysfunction results in part from additional factors, such as altered chest wall and lung mechanics, modifications in the distribution of surfactant, micro-atelectasis, and local fibrosis secondary to recurrent pneumonia.[288] Scoliosis further impairs pulmonary function. On average, for each 10 degrees of thoracic scoliosis curvature, forced vital capacity (FVC) decreases by 4%.[283] In 90% of patients, a curvature of greater than 20 degrees develops 3 to 4 years after they are wheelchair bound. Respiratory failure inevitably occurs in the second decade of life and is the most common cause of death.[289]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Chronic elevation of the serum CPK level is a general indication of muscle disease. Three serum tests showing elevated CPK levels obtained one month apart is diagnostic of muscular dystrophy. CPK represents leakage of enzyme from muscle cells and does not correlate with severity of the disease. CPK could reach 50 to 300 times the normal value in early stages of the disease. The level tends to decrease with the loss of muscle mass. Elevation of the MB fraction of CK precludes its use as a marker for cardiac injury.[282] EMG can be supportive of the diagnosis; however, it can be very difficult to perform on children. Muscle biopsy, followed by immunostaining or Western blot analysis for dystrophin, is recommended for diagnostic testing. Multiple polymerase chain reactions are also useful in detecting more than 98% of the existing deletions.[279] The result is usually available within 24 hours, which may render muscle biopsy, the old "gold standard," obsolete.

ANESTHETIC CONSIDERATIONS

Patients with DMD and BMD may require anesthesia for muscle biopsy, correction of scoliosis, release of contractures, and exploratory laparotomy for ileus,[282] as well as for dental[290] and obstetric[291] procedures. As the natural course of the disease progresses, the risk of surgery increases concomitant with the increased comorbid conditions associated with the later phase of the disease. However, perioperative complications are not proportional to the severity of the disease. They occur even in mildly affected patients. Consequently, patients should undergo careful preoperative consultation and evaluation.

Fifty to seventy percent of patients with muscular dystrophy demonstrate some cardiac abnormality, although it is clinically significant in only ten percent.[282] Preoperative cardiology assessment with an ECG and echocardiography is essential. Continuous cardiac Holter monitoring is necessary if an arrhythmia is captured on the ECG or if the patient describes symptoms that can be related to cardiac arrhythmias. An echocardiography will demonstrate mitral valve prolapse in 10% to 25% of patients. It may also show posterobasilar hypokinesis in a thin-walled ventricle and a slow relaxation phase with normal contraction characterizing the cardiomyopathy seen in DMD.[282] However, echocardiography may not always reflect the ability of the diseased myocardium to respond to perioperative stress. A stress echocardiography using angiotensin to detect latent heart failure and identify inducible contraction abnormalities has been advocated.[292]

An estimated 30% of deaths in individuals with DMD are due to respiratory causes.[293] Therefore careful preoperative pulmonary assessment is important. Webster demonstrated that the manual muscle strength test has a strong statistical correlation with all of the timed functional tests. Peak expiratory flow was not only easy to perform, but also correlated statistically with all timed functional tests.[294] The correlation was not significant for VC or forced expiratory volume in 1 second (FEV_1).

Intraoperatively, in terms of airway management, patients with DMD and BMD may have decreased laryngeal reflexes and prolonged gastric emptying time, which increases the risk for aspiration.[295] Decreased ability to cough up the accumulation of oral secretions predisposes muscular dystrophy patients to postoperative respiratory tract infections.[282] Masseter spasm is also a possible complication during induction of anesthesia in these patients.[296] Preparedness for a difficult airway is necessary, especially in patients with potential airway problems.

Postoperatively, DMD patients are at an increased risk for respiratory compromise.[297] Retrospective reviews have indicated that the incidence of prolonged postoperative ventilation (>36 hours) was greatest in DMD patients who had a preoperative FVC of less than 40% of the predicted value.[298,299] Preoperative pulmonary function studies are valuable in determining the postoperative course. Patients with a VC of greater than 30% of the predicted value can usually be extubated immediately after surgery.[282] Sleep apnea may also compound the condition and contribute to the development of pulmonary hypertension. Continuous positive airway pressure and bilevel positive airway pressure have been demonstrated to be effective in the management of postoperative respiratory depression. Delayed pulmonary insufficiency may occur up to 36 hours postoperatively despite the apparent recovery of skeletal muscle strength.[300]

Reports have suggested a relationship between DMD/BMD and MH, but this association is not based on good rational grounds.[301] Whereas the risk for an MH mutation in DMD/BMD patients is similar to that of the general population, the incidence of MH-like anesthetic events has been reported to be 0.002 with DMD and 0.00036 with BMD. Unexplained cardiac arrest[296,302] and acute heart failure[303] have been reported in DMD/BMD patients. Succinylcholine is contraindicated in these patients because of the potential for rhabdomyolysis and hyperkalemia as a result of their unstable sarcolemmal membranes. Succinylcholine-induced hyperkalemia during acute rhabdomyolysis is more likely to result in cardiac arrest and unsuccessful resuscitation than is the potassium efflux resulting from upregulation of acetylcholine receptors in burn patients.[300] Although the use of nondepolarizing muscle relaxants is usually accompanied by an increase in both maximal effect and duration of action,[304] proper and rapid reversal with sugammadex may put some of these concerns to rest. Current off-label experience in infants and children has been favorable. Narcotics can be used, but small incremental dosing and short-acting medications are recommended given the respiratory depression associated with these medications, as well as the reports of inadvertent reactions to volatile anesthetics,[282]

Recently, TIVA has become more popular.[305] However, consideration needs to be given to the myocardial status of the patient when propofol or barbiturates are used because they may lead to profound hypotension and reduced organ perfusion.[282,306] Regional anesthesia may be a good alternative to general anesthesia because it avoids the risk of triggering agents and respiratory depression and enables the use of local anesthetics for postoperative analgesia. It may also facilitate chest physiotherapy.[307]

Recent breakthroughs in gene therapy are shining new lights into the management of these relatively common disorders. We have not seen reports on anesthesia management for DMD/BMD patients who had received gene therapy.

Limb-Girdle Muscular Dystrophy

Limb-girdle muscular dystrophy (LGMD) is a group of disorders with heterogeneous causes. To date, at least 18 genes have been identified as being responsible for this disease, with 7 being autosomal dominant and 11 autosomal recessive.[308] Mutations within the same gene may result in different phenotypes that sometimes are not consistent with LGMD. Proximal muscle (shoulder or pelvic) girdle weakness is the characteristic feature of this group of diseases. Given the marked genetic heterogeneity, clinical manifestations of the disease vary. Autosomal recessive forms are about 10 times more common than autosomal dominant forms. Fukutin-related protein (*FKRP*) and calpain 3 (*CAPN3*) gene mutations have been associated with LGMD. In addition, a number of other disorders, not strictly included under LGMD in this classification, may have

LGMD-like phenotypes.[308] Sporadic cases of LGMD have been reported in the anesthesia literature.[309-311] General approaches to these patients are the same as those for DMD/BMD.

Myotonic Dystrophy

Myotonic dystrophy (MD) is an inherited muscular disorder characterized by progressive muscle weakness and wasting. Two types of MD result from a mutation in either the dystrophia myotonica–protein kinase (*DMPK*) gene, located on chromosome 19q13.3 (MD1, also known as Steinert disease), or the CysCysHisCys (CCHC)-type zinc finger, nucleic acid binding protein (*CNBP*) gene, located on chromosome 3q21 (MD2).[312]

The incidence of MD is 1 in 8000. MD1 is by far the most common of the two types and accounts for about 98% of all cases. MD1 is caused by expansion of a CTG trinucleotide repeat in the *DMPK* gene and is inherited in an autosomal dominant manner.[312] Typical signs and symptoms include muscle weakness and wasting (most prominent in the cranial and distal limb musculature), periodic myotonia, progressive myopathy, insulin resistance, defects in cardiac conduction, neuropsychiatric impairment, cataracts, testicular atrophy, and frontal balding in males. The typical cranial muscle weakness and wasting are manifested not only in the facial, temporalis, masseter, and sternocleidomastoid muscles but also in the vocal cord apparatus. Mitral valve prolapse is found in 20% of patients.[300] The severity of the disease is related to the number of extra trinucleotide repeats.[94] MD1 patients may also have mildly elevated CK levels. Myotonic discharges can be identified on EMG, as well as an inability to relax from a handgrip. During pregnancy, the symptoms may be exacerbated. Uterine atony and a retained placenta may also complicate vaginal delivery. First-degree atrioventricular heart block is a common finding on the ECG before the onset of symptoms.[300]

MD2 is also called proximal myotonic myopathy. Intron 1 of the *CNBP* gene contains a complex repeat motif, (TG)n(TCTG)n(CCTG)n, and expansion of the CCTG repeat was determined as the cause of MD2. Patients with MD2 suffer from myotonia (90% of those affected), muscle dysfunction (82% weakness, pain, and stiffness), and less commonly, cardiac conduction defects, iridescent posterior subcapsular cataracts, insulin-insensitive type 2 diabetes mellitus, and testicular failure.

There is no case report in the literature linking MD to MH.[313] Lehmann-Horn and associates performed IVCT in 44 patients with myotonias and periodic paralyses, which revealed 4 positive, 10 equivocal, and 30 negative results.[314]

ANESTHETIC CONSIDERATIONS

General considerations for MD are similar to those for other muscular dystrophies. Mathieu and coworkers conducted a retrospective study on the anesthetic and surgical complications of MD. The majority of complications were found to be pulmonary related and significantly more frequent in patients undergoing upper abdominal operations and those with severe disability, as assessed by the presence of proximal limb weakness.[315] The pulmonary complications of MD are the result of hypotonia, chronic aspiration, and central and peripheral hypoventilation.[282] Smooth muscle atrophy, which leads to poor gastric motility, when coupled with a diminished cough reflex, promotes aspiration.

Succinylcholine will produce contractions lasting for several minutes, thus making intubation and ventilation a challenge. These contractions are not antagonized by nondepolarizing muscle relaxants. Other agents, including methohexital, etomidate, propofol, and even neostigmine, may also induce myotonic reactions. Short-acting nondepolarizing muscle relaxants or avoidance of relaxation is therefore advised.[282] Case reports have demonstrated normal responses to sugammadex when rocuronium was used as the neuromuscular blockade.[316-318]

Triggering factors, such as hypothermia, shivering, and mechanical or electrical stimulation, may cause a myotonic reaction.[319] The reaction can be treated with phenytoin (4-6 mg/kg/day) or quinine (0.3-1.5 g/day).[282] Furthermore, MD patients can be very sensitive to anesthetic agents, with hypersomnolence and CO_2 retention sometimes being observed. Careful titration with relatively short-acting anesthetic agents may be beneficial. Close cardiac monitoring is required for MD patients. Pacing equipment should be readily available because a third of first-degree atrioventricular blocks may not respond to atropine.[282] All patients should be treated as though they have both cardiomyopathy and conduction defects.

Myotonia Congenita

Myotonia congenita (MC) is a congenital form of muscular dystrophy characterized by uncontrolled temporary skeleton muscle excitability as a result of mutations in the muscle chloride channel gene (*CLCN1*). There are two forms of MC, one with autosomal dominant and the other with recessive inheritance. The former is also known as Thomsen disease and the later as Becker myotonia. The myotonia in MC patients is usually initiated by a forceful muscle contraction, particularly after being at rest for at least 10 minutes. The myotonic muscle stiffness then becomes increasingly obvious after a second and third short, but forceful contraction. Further contractions usually dampen the myotonia.[320]

Thomsen disease was the first myotonic disease to be described. Patients may have a hypertrophic and athletic appearance. The sign of percussion myotonia is described as an indenting-appearing myotonia triggered by tapping the muscle. Lid lag is common and muscle stretch reflexes are normal.[320] Myotonia symptoms in Becker myotonia usually start at 10 to 14 years of age or even later and are more severe than those of Thomsen disease. Becker myotonia may be associated with severe generalized stiffness resulting in falling. It can frequently be misdiagnosed as epilepsy. Antiepileptic medications do improve the symptoms, however.[320]

ANESTHETIC CONSIDERATIONS

As with many muscle diseases, there have been reports that MC patients are predisposed to MH, but as is the case for almost all of them, there are no data to support this hypothesis.[321-323] However, depolarizing muscle relaxants can lead to severe masseter spasms in MC patients. Generalized spasms involving the respiratory and skeletal muscles have been reported.[321] The findings resemble those of MH, so dantrolene is sometimes administered.[320] Because dantrolene is an inhibitor of calcium release from the SR, it can usually abolish the myotonia effectively.[321,322] Some believe that local anesthetics and class Ib antiarrhythmic drugs such as lidocaine should be used for myotonic reactions rather than dantrolene.[324] Because shivering in the operating room can trigger the myotonic reaction, MC patients should be kept normothermic during surgery.[320]

Myotubular Myopathy

Myotubular myopathy (MTM) is pathologically defined by the presence of centrally placed nuclei in the majority of extrafusal muscle fibers, an appearance resembling fetal myotubes during normal muscle development. Consequently, MTM is also called centronuclear myopathy (CNM).[325] However, MTM now mostly refers to the X-linked form of the disease, whereas CNM is used for the autosomal form.[325]

MTM and CNM are rare. The estimated incidence of MTM is 1 in 50,000 newborn males.[325] MTM has been linked to the myotubularin (*MTM1*) gene on Xq28. Pregnancy is often complicated by polyhydramnios and reduced fetal movements. Affected males typically have severe floppiness and weakness and respiratory distress at birth. Cardiac muscles are not generally involved. The patient usually has a normal response to pain, but tendon reflexes are absent. The long-term prognosis for MTM is extremely poor.[325] In patients who survive the first year of life, most are either completely or partially ventilator dependent.[326] These patients often have abnormal liver function.[326] Both autosomal recessive and autosomal dominant forms have been observed in CNM patients. Its clinical features include respiratory distress, hypotonia, bulbar weakness, ophthalmoplegia, ptosis, and facial diplegia. Although the exact genetic mechanism is not fully understood, the *MTM1*, myotubularin-related protein (*MTMR2*), and myotubularin-related phosphatase (*MTMR3*) genes have been implicated.[325] Pathologically, MTM and CNM share a similar, characteristic histologic feature: predominantly type 1 fiber with centrally placed nuclei seen on hematoxylin-eosin staining of formalin-fixed, paraffin-embedded tissue.[325]

ANESTHETIC CONSIDERATIONS

Reports of anesthesia for patients with MTM are sparse.[327-332] Nontriggering general anesthesia has been used because of the unfounded concern of possible susceptibility to MH. Agents such as propofol, fentanyl, remifentanil, and nitrous oxide have been used successfully without adverse effects.[327-332] The possibility of a prolonged effect of nondepolarizing muscle relaxants has been suggested with mechanomyography.[327-332] However, in reality, intubation of such patients may not require any muscle relaxant because of their hypotonic state. Costi and van der Walt suspected that the defect in MTM is distal to the neuromuscular junction,[328] whereas Dorchies and coworkers suggested that muscles in MTM might be intrinsically normal, with myotubularin-deficient motor neurons involved in development of the disease.[333]

Metabolic Myopathies

Two major energy sources for muscle exist: glycogen and fatty acid. Glycogen serves as a dynamic, but limited reservoir of glucose, mainly stored in skeletal muscle and liver. Glycogen storage disorders (GSDs) are a group of metabolism disorders caused by enzyme deficiency or dysfunction. They reduce effective glucose storage by interfering with normal glycogen synthesis and degradation. Synthetic errors cause decreased normal glycogen, whereas degradation errors tend to block the breakdown of glycogen. Subsequently, hypoglycemia and accumulation of glycogen in tissues could occur as a result of substrate use. There are more than 12 types of GSD that are assigned roman numerals based on the enzyme deficiencies. Types I and II are discussed here.

Glycogen Storage Disease Type I

The incidence of GSD I is approximately 1 in 100,000 live newborns.[334] The incidence in non-Ashkenazi Jews from North Africa may be as high as 1 in 5420 people.[334] The defective enzyme causing the disease is glucose-6-phosphatase, which is the enzyme that converts glucose 6-phosphate (G6P) to glucose in the liver. Type Ia (von Gierke disease) is due to a deficiency in G6P hydrolase (catalytic subunit) activity and accounts for more than 80% of cases. Types Ib (G6P transporter deficiency), Ic, and Id represent allelic defects in the translocase associated with G6P. Their inheritance is autosomal recessive. The G6P gene (*G6PC*) encoding the hydrolase resides at 17q21, with the gene encoding G6P translocase (*G6PT*) located at 11q23. Mutations responsible for GSD I have been described in both type Ia and Ib patients.[334]

Impaired glycogenolysis results in accumulation of glycogen and G6P in the liver, kidney, intestine, skeletal muscle, and heart and is manifested as hepatomegaly, renomegaly, proximal tubular dysfunction, and diarrhea.[335] Fasting hypoglycemia is the initial manifestation of the disease. As a result, upregulation of the synthesis and transport of counter-regulatory hormones, such as glucagon, cortisol, catecholamines, and growth hormone, becomes obvious and leads to the release of pyruvate, lactate, and free fatty acid. Lipid deposition in lean tissues such as the liver, skeletal muscle, cardiac muscle, and pancreas results in lipotoxicity and organ failure, including pulmonary hypertension, steatohepatitis, end-stage renal disease, insulin resistance, cardiac contractile dysfunction, and pancreatic β cell failure.[334] For type Ib disease, specific problems such as neutropenia and neutrophil dysfunction are prominent. Patients may have recurrent infections and inflammatory bowel disease.[336]

ANESTHESIA CONSIDERATIONS

Anesthesia case reports for GSD I patients are rare.[337,338] Patients with GSD I diseases should be given intravenous glucose-containing fluid preoperatively when they have fasted. Lactate-containing solutions should be avoided because these patients are not able to convert the lactic acid to glycogen.[282] Patients need to be monitored frequently to avoid hypoglycemia.

Glycogen Storage Disease Type II (Acid Maltase Deficiency)

The incidence of acid maltase deficiency (AMD) is estimated to be 1 in every 14,000 to 40,000 births. Its inheritance is autosomal recessive with a few exceptions.[339,340] Mutations of the acid maltase gene on chromosome 17q25 cause deficiency of lysosomal acid maltase (acid α-1,4-glucosidase).[340] Cases of AMD have been arbitrarily classified into three groups—infantile, childhood, and adult—according to the age at onset or death, rate of progression, and tissue-organ involvement.[340]

Acid maltase is a lysosomal enzyme that catalyzes the one-way hydrogenation of glycogen to G6P and is found in all tissues, including skeletal and cardiac muscle.[341] Consequently, glycogen accumulates within the muscle tissues of maltase-deficient patients. Infantile AMD, also known as Pompe disease, is usually manifested within the first few months of life as rapidly progressive weakness and hypotonia and enlargement of the tongue, heart, and liver. Massive amounts of glycogen (8%-15% of the wet weight of the tissue) accumulate in the heart, liver, and skeletal muscle, with relatively smaller deposits in smooth muscle, eyes, kidneys, endothelial cells, lymphocytes, brain, and spinal cord. Accumulation of glycogen in cardiac muscle leads to cardiac failure in the infantile form.[340] Echocardiography demonstrates marked thickening of the interventricular septum and posterior left ventricular wall, left ventricular outflow obstruction, and trabecular hypertrophy.[340] Ventricular wall thickness may be increased to up to 25 mm.[342] Wolff-Parkinson-White syndrome has been reported.[343] The signs and symptoms of infantile AMD may resemble those of DMD. Death usually results from cardiorespiratory decompensation within several years of disease progression.[344]

Childhood AMD occurs in infancy to early childhood and is manifested by clinical signs of myopathy. Respiratory muscles tend to be selectively affected. Calf enlargement can also occur. The disease progresses relatively slowly in this form, with a few patients surviving beyond the second decade of life.[340] Tongue, heart, and liver enlargement occur infrequently.[345] However, involvement of vascular smooth muscle is more severe than in the infantile form. There has been a report of extensive glycogen deposition in the arterial wall causing basilar aneurysms.[345]

Adult AMD usually occurs after age 20 and is characterized by slow progressive myopathy or symptoms of respiratory failure.[340] The weakness in proximal muscles is more prominent than the weakness in distal muscles. A third of adult AMD patients suffer from respiratory failure with a restrictive pattern. Weakness in the diaphragm causes extensive atelectasis. VC may be significantly reduced.[340]

ANESTHETIC CONSIDERATIONS

Anesthesia reports in AMD patients are rare.[346-349] Isolated intraoperative cardiac arrest during halothane anesthesia in infantile AMD has been documented.[349] Despite the problem noted with halothane, enflurane[347] and sevoflurane[348] have been used without complications. Theoretically, total intravenous general anesthesia with propofol may cause a reduction in afterload leading to an increased risk for myocardial ischemia. This may become significant when the patient is tachycardic.[348]

Subendocardial ischemia may occur in patients with a thickened ventricular wall and results in higher left ventricular end-diastolic pressure at lower ventricular volume.[348,350] Close cardiac monitoring is therefore necessary. A central venous or pulmonary artery catheter is not essential in patients who are normovolemic without preexisting heart failure.[348] Adequate filling pressure and normal to high systemic vascular resistance (SVR) are required to ensure effective coronary perfusion.[348] Ketamine has been used successfully in a number of cases because of its ability to maintain SVR and contractility. Respiratory failure and muscle weakness are the other concerns for anesthesiologists. A spectrum of uses of muscle relaxants from none[347] to atracurium[346] to rocuronium[348] have been attempted. Low-dose rocuronium, 0.5 mg/kg, with close monitoring of neuromuscular function and adequate use of reversal agents, has been sufficient to prevent prolonged postoperative weakness.[348] Depolarizing agents should be avoided because of the potential risk of hyperkalemia and rhabdomyolysis.[348,349]

Mitochondrial Myopathies

Mitochondrial diseases refer to defects in the five main steps of mitochondrial metabolism: substrate transport, substrate utilization, the Krebs cycle, the electron transport chain, and oxidation-phosphorylation coupling.[351] However, the term *mitochondrial myopathy* has been reserved for disorders caused by defects in the respiratory chain.[351] The respiratory chain is composed of five multimeric complexes (I-V) embedded in the inner mitochondrial membrane, plus two small mobile electron carriers, coenzyme Q_{10} (CoQ_{10}) and cytochrome *c*, for a total of more than 80 proteins,[351] among which 13 are encoded by mitochondrial DNA (mtDNA) and all others by nuclear DNA (nDNA). mtDNA is different from nDNA in several aspects: (1) mtDNA is circular and contains no intron, (2) it has larger numbers of copies than nDNA does and a much higher spontaneous mutation rate, and (3) its inheritance is maternal. Diagnosis of mitochondrial diseases is difficult because of their clinical heterogeneity.

Primary mtDNA mutations may include point mutations in polypeptide, tRNA, or rRNA encoding regions and large-scale rearrangements, duplications, or deletions.[352] Some of the common conditions caused by point mutations include myoclonic epilepsy with ragged-red fibers (MERRF); mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS); neuropathy, ataxia, and retinitis pigmentosa (NARP); maternally inherited Leigh syndrome; and Leber hereditary optic neuropathy.[351] Sporadic large-scale mutations may lead to Kearns-Sayre syndrome, progressive external ophthalmoplegia, and Pearson syndrome.[351] nDNA mutations can cause deficiencies in complexes I to IV and CoQ_{10} of the electron transport chain.[351]

Mitochondrial diseases present a diagnostic challenge due to their clinical heterogeneity. Since mitochondria are ubiquitous; every tissue in the body can be affected by mtDNA mutations. Disorders due to nDNA mutations follow a Mendelian pattern and are thus phenotypically “all or none,” while inheritance of mtDNA is stochastic, leading to greater variability. Mitochondrial myopathy is estimated to have an incidence of 1 in 4000.[353] Among all the mitochondrial functions, abnormalities in electron transport and oxidative phosphorylation are the most common causes of mitochondrial myopathies.[354] Mitochondrial myopathies are characterized by proximal muscle weakness. Common laboratory findings include a very high lactate to pyruvate ratio (50-250:1 instead of a normal ratio of <25:1), increased blood levels of free carnitine, and occasionally low levels of folate (for instance in Kearns-Sayre syndrome). The hallmark of mitochondrial myopathies is the "ragged red fiber" when muscle biopsy specimens are stained with modified Gomori trichrome stain,[355] and specific defects in the activity of these enzymes have been demonstrated in patients with mitochondrial disease.[356] Fatigue and poor stamina are prominent clinical features. Movement disorders such as ataxia, dystonia, myoclonus, chorea, athetosis, and tremors have also been described as being due to mitochondrial abnormalities.[356] CT and MRI scans of the brain may be very helpful—for example, patients with MELAS demonstrate basal ganglia calcifications and stroke-like patterns not confined to vascular territories.[357] Clinical features of two relatively common encephalomyopathies, MELAS and MERRF, are briefly discussed below.

MITOCHONDRIAL MYOPATHY, ENCEPHALOPATHY, LACTIC ACIDOSIS, AND STROKE-LIKE EPISODES

MELAS is the most common mitochondrial encephalomyopathy. Onset is most commonly before age 20. Seizures are common and stroke-like episodes ("stroke-like" because they do not conform to vascular distributions) may produce hemiparesis, hemianopia, and cortical blindness. Any patient with a stroke below the age of 40 should be worked up for MELAS. Associated findings include diabetes mellitus, hearing loss, pituitary and thyroid hypofunction, and lack of secondary sexual characteristics. In its full expression, MELAS leads to dementia, a bedridden state, and death. There is no specific treatment.[358]

MYOCLONIC EPILEPSY WITH RAGGED RED FIBERS

MERRF is a multisystem disorder characterized by myoclonus, generalized epilepsy, ataxia, and ragged red fibers on muscle biopsy. Other clinical features may include hearing loss, peripheral neuropathy, optic atrophy, dementia, short stature, and exercise intolerance.[359] Cardiomyopathy is occasionally present. Laboratory features include an increased lactate at rest and exercise, and a myopathic picture on EMG and electroencephalogram showing generalized spike and wave discharges with background slowing. Only supportive treatment is available.

ANESTHETIC CONSIDERATIONS

The anesthesiologist may be involved in the care of patients with mitochondrial disease in multiple situations—often in the setting of obtaining a muscle biopsy in a child with an undiagnosed myopathy.[360] These patients may also present for surgery for procedures related to the disease (such as implantation of a permanent pacemaker in a patient with KSS[361]), for incidental medical problems, as well as in the labor and delivery suite for labor analgesia.[362] The diversity of clinical presentations encountered in the mitochondrial myopathies discourages a "one size fits all" approach to anesthesia. Rather, each patient should be thoroughly evaluated and the anesthetic plan tailored to the patient's specific needs.

PREOPERATIVE EVALUATION

Given the heterogeneous types of mitochondrial disease, patients with mitochondrial disease will need a comprehensive preoperative evaluation with a particular focus on neurologic, cardiac, respiratory, musculoskeletal, endocrinopathic, and metabolic compromise. An ECG and echocardiogram should be considered in patients with signs and symptoms of cardiomyopathy or conduction defects (or both). Although normal lactate and glucose levels cannot rule out mitochondrial diseases, laboratory studies consisting of glucose, electrolytes with anion gap, complete blood count, blood urea nitrogen, lactate, pyruvate, ammonia, CK, biotinidase, acyl carnitines, and blood and urine amino and organic acids could be used as initial investigation for suspected mitochondrial disorders.[363] Further workup should include an erythrocyte sedimentation rate, glycosylated hemoglobin (HbA_{1C}), liver and renal profiles, thyroid function tests, arterial blood gas, and urinalysis.[353,356] Multidisciplinary consultation with special laboratory and imaging studies may be required.[356]

INDUCTION AND MAINTENANCE OF ANESTHESIA

Anesthesia has a significant impact on mitochondrial function. Both barbiturates and propofol inhibit complex I of the electron transport chain.[363] Local anesthetics have been demonstrated to disrupt oxidative phosphorylation and decrease the bioenergetic capacity of mitochondria.[363] Sensitivity to intravenous barbiturates and etomidate has been reported.[364,365] Fortunately, notwithstanding the potential pitfalls mentioned above, almost every anesthetic technique has been safely used in patients with mitochondrial disease.[366,367] Midazolam,[368] thiopental,[369] propofol,[370,371] remifentanil,[372] and ketamine[371] have all been used safely. Notably, propofol and midazolam are known to inhibit the mitochondrial respiratory chain in a dose-dependent manner.[373] Indeed, mitochondrial dysfunction has been postulated as a mechanism for the propofol infusion syndrome.[374] It is safe to use propofol as an anesthetic induction agent, but the use of a propofol infusion for long periods should probably be avoided.

Premedication should avoid respiratory depression caused by impaired respiratory responses to hypoxemia. Volatile agents such as halothane, isoflurane, and sevoflurane have been shown to inhibit complex I.[363] This direct inhibition of mitochondrial electron transport system enzymes and altered mitochondrial bioenergetics in the heart were thought to be the mechanism of cardiac preconditioning by volatile anesthetics.[375,376] Inhaled sevoflurane has been widely used for induction because of its low pungency.[377] In some cases, halothane[368] and isoflurane[368,378] have also been used. Isoflurane has been recommended as the agent of choice in patients with Kearns-Sayre syndrome because rhythm disturbances have been reported with halothane in such patients.[368,378] In addition, artificial pacing capability is recommended when dealing with this specific subset of patients.[377] With use of the bispectral index, higher sensitivity to volatile agents has been suggested in children with mitochondrial diseases, especially with dysfunction of complex I.[379] However, its methodology has been criticized.[380] A decreased minimum alveolar concentration of halothane in patients with mental retardation has also been reported.[381]

Despite no real evidence and the fact that volatile anesthetics are frequently the anesthetic of choice when muscle relaxants are considered, several papers have expressed concern that these myopathies are associated with increased sensitivity to MH. This conclusion is not supported by any data. Increased sensitivity to nondepolarizing muscle relaxants has been documented for mivacurium,[382] atracurium,[383] and rocuronium.[383,384] In contrast, normal responses to depolarizing and nondepolarizing neuromuscular blockers such as pancuronium,[385] vecuronium,[386] and atracurium[370,387] are also reported. Although muscle relaxants are not absolutely contraindicated based on current literature and research, it is necessary for anesthesia practitioners to cautiously administer depolarizing or nondepolarizing neuromuscular blockers to those patients with mitochondrial diseases and to use neuromuscular monitoring.[353] Presently, there is no evidence to support an association between MH and mitochondrial disease. However, it may be prudent to avoid succinylcholine in patients with extensive myopathy to minimize the risk of hyperkalemia, although the safe use of succinylcholine has been documented in at least one patient with KSS.[385]

Nonsteroidal antiinflammatory drugs[377] and regional techniques consisting of local,[377,388] spinal,[389] and epidural administration have been reported. However, it is suggested that regional anesthesia be performed when neurologic abnormalities of the spinal cord and peripheral nerves have definitely been ruled out.[389] Importantly, coagulation function should be assessed because of the possibility of hepatic dysfunction.[377]

Opioids should be used with caution because of the increased risk for respiratory depression and their potential to induce respiratory acidosis in addition to the underlying metabolic acidosis.[377] Because patients with mitochondrial diseases have dysfunctional aerobic metabolism, any increase in the basic metabolic rate should be prevented.[356] Shivering, hypoxia, fasting, and hypotension in such patients may exacerbate the lactic acidosis and should therefore be avoided.[390] Finally, the increased postoperative infection rate in patients with mitochondrial diseases may be due to low hepatic mitochondrial activity, phagocytosis by Kupffer cells, and decreased activity of the reticuloendothelial system.[391]

Perhaps more important than the specific choice of anesthetic agents are the implications of patients' comorbidities and metabolic status. Normothermia should be maintained during surgeries, and intravenous fluids should be warmed to body temperature. Lactated Ringer (LR) should probably be avoided given the risk of preexisting lactic acidosis (although there is no evidence that LR has worsened acidosis when it has been used[366]). There have been multiple reports of hyponatremia (and occasional hyperkalemia) in these patients.[366,392,393] Adrenal insufficiency should be considered in such a picture, particularly when accompanied by hypotension.[366] Finally, these patients are at increased risk of cardiac conduction abnormalities and cardiomyopathy that should be taken into consideration while formulating an anesthetic plan (Box 35.7).

BOX 35.7 **Perioperative Considerations for Patients with Mitochondrial Disease**

1. Carefully assess and document the extent of organ system involvement preoperatively (including cardiac abnormalities in the KSS patients).
2. Minimize fasting period, avoid hypovolemia and glucose store depletion.
3. Minimize perioperative stress that may provoke increased energy requirement.
4. Pay particular attention to perioperative temperature control given that the mitochondrial respiratory chain is responsible for thermogenesis.
5. It is reasonable to administer glucose-containing solutions perioperatively, and to avoid lactate-containing fluids (e.g., lactated Ringer solution), particularly in children who are prone to lactic acidosis.
6. Every class of anesthetic agents is associated with theoretical risk of complications, but both volatile anesthetics and propofol have been successfully used in these patients.
7. Although there is no clear evidence of an association between malignant hyperthermia and mitochondrial disease, it is important to avoid succinylcholine.
8. Neuraxial anesthesia can be considered, but requires careful attention to preoperative neurologic dysfunction.

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disorder of the neuromuscular junction. Autoantibodies against the α-subunit of the muscle-type nicotinic acetylcholine receptor destroy acetylcholine receptors of the neuromuscular junction and cause classic transmission failure with muscle weakness and fatigue. Sparing of other α-subunits of neuronal-type nicotinic acetylcholine receptors provides an explanation for the lack of autonomic or CNS involvement of the disease. The incidence of MG varies between geographic regions, being 1.2 per million in Japan and about 14 per 100,000 in some areas of the United States.[394,395] In younger age groups, females are affected more often than males, whereas in elderly age groups (>60 years), males are more frequently affected.

There is a striking association between MG and hyperplasia of the thymus, with more than 70% of MG patients having thymus hyperplasia and 10% having thymomas.[395] MG may also be seen as a part of a paraneoplastic syndrome.[395]

Typically, patients first report bulbar symptoms consisting of diplopia and ptosis. The bulbar symptoms are often followed by unevenly distributed muscle weakness and fatigue of the extremities and face. Speech and chewing may be affected, as well as pharyngeal function and coordination of swallowing, with a subsequent increased frequency of aspiration of oral contents. The muscle weakness is often

BOX 35.8 Risk Factors of Postoperative Ventilation for Patients with Myasthenia Gravis[396]

Vital capacity <2-2.9 L
Duration of MG >6 years
Pyridostigmine dosage >750 mg/day
History of chronic pulmonary disease
Preoperative bulbar symptoms
History of myasthenic crisis
Intraoperative blood loss >1000 mL
Serum antiacetylcholine receptor antibody >100 nmol/mL
Pronounced decremental response on low frequency repetitive nerve stimulation

MG, Myasthenia gravis.
Modified from Anesthesia for the patient with myasthenia gravis. https://www.uptodate.com/contents/anesthesia-for-the-patient-with-myasthenia-gravis; 2018. Accessed April 8, 2019.

exacerbated during exercise and throughout the course of the day. Apart from the patchy distribution of muscle weakness, symptoms may also vary from day to day, and there may be periods of remission of varying duration.

The diagnosis of MG is made by neurologic examination and testing of the tendency to fatigue and exhibit increased weakness during exercise or repeated contractions. The diagnosis can be confirmed by the Tensilon test (administration of an anticholinesterase, e.g., edrophonium). Improvement is usually seen within 5 minutes after administration of the drug and lasts for about 10 minutes. In addition, electrophysiologic evaluation is often performed and shows a classic decrement in the compound muscle action potential after repetitive nerve stimulation (Box 35.8).[396]

ANESTHETIC CONSIDERATIONS

Ideally, careful neurologic consultation in addition to preoperative evaluation should be performed on MG patients with the aim of optimizing drug therapy and preparing for postoperative care. Pulmonary function tests may be indicated to determine the need for mechanical ventilation postoperatively.[382] In addition, a number of risk factors have been associated with the necessity for postoperative ventilation.

As a general rule, patients should keep taking their anticholinesterase medication and be informed about the possibility of postoperative ventilator support. Succinylcholine can be used if needed for rapid tracheal intubation. However, patients with MG might need larger than normal doses (1.5-2.0 mg/kg body weight) because of the decreased number of functional acetylcholine receptors.[397] On the other hand, as a result of the decrease in cholinesterase activity achieved by anticholinesterase treatment, neuromuscular blocks with succinylcholine or mivacurium are frequently prolonged.[398,399] Traditionally, nondepolarizing neuromuscular blockers can be used in patients with MG but should be given with caution because their effects are highly unpredictable and the distribution of muscle weakness is often uneven. Most anesthesiologists used to dose nondepolarizing muscle relaxants in small increments corresponding to 0.1 to 0.2 times the 95% effective dose (ED_{95}) until the desired neuromuscular blocking effect is achieved. Perioperative anticholinesterase treatment will modify the response to traditional reversal agents, because of the already existing acetylcholinesterase block, and in some cases, will reportedly prolong the recovery of neuromuscular function after the administration of a reversal agent.[400] With the adoption of a newly modified γ-cyclodextrin neuromuscular reversal agent, sugammadex, the management of airway and steroidal neuromuscular blockade agents, such as rocuronium or vecuronium, becomes simplified in patients with MG.[401,402]

Sugammadex has a lower affinity to vecuronium than rocuronium; however, the reversal with sugammadex for vecuronium is still very satisfactory because fewer vecuronium molecules are present for equivalent blockade due to its higher potency to rocuronium. Although FDA has not approved its use in pediatric populations, current reported cases were favorable. On a separate note, sugammadex does have conflicting effects on progesterone, cortisol, aldosterone, and testosterone levels and may alter some coagulation parameters such as activated thromboplastin time and prothrombin time, or INR.[403]

Potent volatile anesthetics have been used successfully in MG patients. Because of the impaired margin of safety at the neuromuscular junction, a volatile anesthetic usually provides adequate muscular paralysis to allow most surgical procedures to be performed without the need for a neuromuscular blocking agent. Epidural and spinal anesthesia can be used in MG patients in addition to general anesthesia, provided that muscle function and ventilation are carefully monitored perioperatively. For a more detailed review, see Baraka[404] and Abel and Eisenkraft.[405]

EATON-LAMBERT MYASTHENIC SYNDROME

Eaton-Lambert myasthenic syndrome (ELMS) is an immune-mediated channelopathy caused by decreased release of acetylcholine as a result of autoantibodies against presynaptic voltage-gated calcium channels and other presynaptic elements.[406] Patients with ELMS have muscle weakness and fatigability, generally of the proximal limb muscles, with the lower extremities affected more often than the extraocular and bulbar muscle groups. The syndrome is frequently part of a paraneoplastic phenomenon, usually combined with small cell lung carcinoma. Unlike MG, patients with ELMS are usually worse in the morning with gradual improvement throughout the day. Improvement of muscle function with exercise is due to the accumulation of presynaptic calcium and subsequent improved release of acetylcholine.[407] A minority of patients exhibit autonomic dysfunction. The diagnosis of ELMS is made by careful physical examination combined with clinical electrophysiology showing the typical facilitation of motor action potential with high-frequency nerve stimulation (30-50 Hz). Anticholinesterase treatment has little effect on patients with ELMS. Plasmapheresis, immunoglobulin therapy, and 3,4-diaminopyridine (DAP) result in transient improvement.

ANESTHETIC CONSIDERATIONS

As in patients with MG, those with ELMS should be carefully evaluated for the risk of postoperative respiratory failure and the need for prolonged respiratory monitoring in the postoperative period. Sensitivity to depolarizing and nondepolarizing NMBA is usually increased. In patients treated with DAP or an anticholinesterase agent, reversal of a neuromuscular blockade may be ineffective.

Periodic Paralysis (Hyperkalemic, Hypokalemic, and Normokalemic)

The periodic paralyses are a group of disorders that are characterized by alterations of function in voltage-gated ion channels; hence these diseases are sometimes termed "skeletal muscle channelopathies."[408] The symptomatology of the particular channelopathy depends on the specific ion channel involved and can be divided into three broad categories: (1) chloride channelopathies (myotonia without paralysis e.g., MC, see earlier), (2) sodium channelopathies (myotonia with paralysis, such as hyperkalemic periodic paralysis [HyperPP]), and (3) other cation channelopathies (paralysis without myotonia, such as hypokalemic periodic paralysis [HypoPP]).[409]

HyperPP is an autosomal dominant disorder first described by Tyler and associates in 1951.[320] It is characterized by attacks of flaccid weakness associated with increased serum potassium.[410] Precipitating factors include potassium rich foods, and rest after exercise. In addition, a cold environment, emotional stress, fasting, glucocorticoids, and pregnancy can provoke or worsen the attacks. The paralysis may last for 15 minutes to an hour, with decreased tendon reflexes. In the interictal state, HyperPP is usually associated with mild myotonia that does not impede voluntary movements.[320]

The pathogenesis of HyperPP involves mutations in *SCN4A*, encoding the voltage-gated sodium channel $Na_V1.4$ of mature muscle fibers; and such mutations lead to pathologically increased sodium current and an increased tendency of the muscle fiber to become depolarized.[320,410] Influx of sodium into the muscle is accompanied by simultaneous efflux of potassium and hyperkalemia. Mutant channels exhibit sustained sodium currents that lead to prolonged membrane depolarization, which will then cause myotonia followed by membrane desensitization (or inactivation) and will eventually result in paralysis. In HyperPP patients, serum CK can be elevated, sometimes 5 to 10 times above the normal limit, whereas serum sodium and potassium levels are normal in the interictal state.[320] EMG recordings will often show myotonic discharges during and between attacks. Muscle biopsies may show small peripheral vacuoles in the sarcoplasm. Recent studies supported that normokalemic periodic paralysis is a variant of the HyperPP, not a distinct disease, because all the subjects exhibited clinical and laboratory features of the HyperPP.[411-413] Treatment includes medication with acetazolamide (a carbonic anhydrase inhibitor) and mexiletine (an antiarrhythmic with a mechanism of action similar to lidocaine). Behavioral modification, such as avoiding potassium containing foods, strenuous exercise, fasting, and exposure to cold are also important.[409]

HypoPP is characterized by a decrease in potassium levels in blood. Attacks of HypoPP can be triggered by rigorous exercise, stress, high-carbohydrate or high-salt meals, pregnancy, menstruation, hypothermia, or drugs such as insulin.[414,415] EMG does not usually show myotonia.[410] The severity of attacks is usually greater than those occurring in patients with HyperPP. HypoPP is an autosomal dominant disease with higher penetration in males. The disease is due to loss of function of one of the two different ion channel types: $Ca_V1.1$ and $Na_V1.4$.[410] The most common muscle groups affected are those in the arms and legs; however, the disorder can also affect swallowing and respiratory muscles, which can be fatal in severe cases. The diagnosis of HypoPP is made by laboratory tests demonstrating hypokalemia during attacks and normokalemia between attacks. Mutations in the skeletal muscle voltage-gated calcium channel encoded by *CACNA1S* (HypoPP type 1) and *SCN4A* (HypoPP type 2) have been identified.[313] Theoretical association of HypoPP to MH was made because a few MH patients were known to have mutations in the *CACNA1S*.[313] It is generally accepted that the risk of susceptibility of HypoPP patients to MH is similar to that of the general population. It is still unclear the exact mechanisms that lead to hypokalemic paralysis. It is important to remain aware of the differences in the clinical features between HyperPP and HypoPP. HypoPP is not associated with myotonia, a spontaneous attack is associated with hypokalemia (a diagnostic criterion), potassium is a remedy, and glucose triggers an attack.[409] Treatment is centered on the identification and avoidance of triggers. Potassium administration can be useful in the treatment of an acute attack. The prophylactic medication of choice in HypoPP type 1 is acetazolamide[416]—however, acetazolamide can worsen symptoms in type 2 HypoPP.[417] Such patients may respond to potassium-sparing diuretics such as spironolactone.[418]

Clinically resembling HypoPP, thyrotoxic periodic paralysis (TPP) occurs later in life than HypoPP. It has a strong male predominance, and is much more common in patients of oriental descent. Loss of function mutations in the inward rectifying potassium channel ($K_{ir}2.6$) may be involved in some cases of TPP.[419] The condition responds to antithyroid medications such as methimazole.[409]

ANESTHETIC CONSIDERATIONS

Potassium, cholinesterase inhibitors, and depolarizing muscle relaxants will aggravate the myotonia in HyperPP patients.[320] Prolonged muscle weakness has been reported when succinylcholine is used.[420] Although one third of patients had no signs of myotonia,[421] masseter spasm and respiratory and skeletal muscles stiffness could still occur during intubation and ventilation.[320] Therefore neostigmine and succinylcholine should be contraindicated in HyperPP patients. Nondepolarizing muscle relaxants may be safely used.[422,423] The safe use of both volatile agents and propofol has been documented.[422-424] Ideally, all patients with HyperPP need to be admitted preoperatively so that proper preoperative fasting can be accompanied by the administration of dextrose-containing potassium-free maintenance fluid.[423] Postoperatively, HyperPP patients may remain paralyzed for up to several hours. Preventive measures such as maintaining normal body temperature and low serum potassium levels and avoiding hypoglycemia are helpful in limiting such paralysis.[422] Although patients with sodium channel pathology have often been considered to be susceptible to MH, there is no increased risk for MH in these patients.[314] General anesthesia with and without nondepolarizing muscle relaxants has been shown to have satisfactory outcomes.[420,422,423,425,426] Regional techniques may also be appropriate for this patient group.[421,425,426] Abortion of the hyperkalemic attack may be accomplished by administering glucose, insulin, epinephrine, and calcium supplements, or, alternatively, glucagon may be used. β-Adrenergic treatment with metaproterenol has also been shown to prevent attacks and facilitate recovery.[423]

Management of HypoPP patients should focus on avoiding triggers and medications causing a shift of potassium. General anesthesia, postoperative stress, glucose-containing intravenous solutions, and long-acting neuromuscular blockers are associated with postoperative paralytic events.[414] Patients with HypoPP undergoing general anesthesia have been reported to exhibit weakness and respiratory distress in the postoperative period.[427,428] While safe use of intermediate and short-acting nondepolarizing muscle relaxants, such as atracurium and mivacurium, have been documented,[429-431] and it is probably prudent to avoid long-acting muscle relaxants.[432] Epidural analgesia has been shown to reduce both pain-related hyperventilation and serum catecholamines, thereby minimizing changes in serum potassium levels.[414] The sympathomimetic effect of epinephrine-containing local anesthetics may also precipitate hypokalemia.[414] Unlike HyperPP, an association between HypoPP and MH cannot be categorically ruled out,[433] although the use of isoflurane in HypoPP has been reported.[431] There are a number of reports of MH-like metabolic crises in patients with HypoPP.[434-436] Contracture-like responses to succinylcholine have also been described.[437] In one of the above descriptions, it seemed likely that there were two unrelated mutations conferring both HypoPP and sensitivity to MH in the same patient.[436] Therefore while the probability of MH in a given patient with HypoPP is likely to be remote, it cannot be ruled out, and the safest course might be the use of a nontriggering anesthetic. If volatile agents are used, they should be used with extra vigilance.[433]

Summary

MH is a subclinical myopathy featuring an eerie and erratic metabolic mayhem that is unmasked on exposure to potent volatile anesthetics or succinylcholine. Skeletal muscle acutely and unexpectedly increases its sarcoplasmic Ca^{2+} concentration, thereby leading to increased oxygen consumption and lactate production, and resulting in greater heat production, respiratory and metabolic acidosis, muscle rigidity, sympathetic stimulation, and increased cellular permeability. MHS skeletal muscle differs from normal muscle in that it is always closer to loss of control of Ca^{2+} concentration within the muscle fiber, and it can involve a generalized alteration in cellular or subcellular membrane permeability. This is an EC coupling defect resulting from an alteration in protein-protein interaction in the CRU. It is a homozygous, single point mutation of *RyR1* in swine and a heterozygous disorder in humans, in whom there may also be a modification of RyR1 protein function by interacting structures, membranes, or enzymes. Diagnosis rests on acute awareness of the signs and symptoms of this syndrome, of which hyperthermia is a late sign. Specific treatment includes administration of dantrolene to lower muscle Ca^{2+} levels, and symptomatic treatment consists of reversal of the acid-base and temperature changes. Evaluation of affected families is guided by analysis of drug-induced muscle contractures (by European IVCT and North American CHCT protocols) and genetic testing of DNA samples. General or regional anesthesia is safe for patients susceptible to MH, provided that care is taken to specially prepare the anesthesia machine and avoid all potent volatile anesthetics and succinylcholine. Research on MH has yielded insight into the physiology of metabolism and into the molecular biology of genetic muscle disorders. Challenges that remain include identification of all genetic mutations responsible for human MH, elucidation of the mechanism that links exposure to subsequent loss of control of Ca^{2+}, development of noninvasive and nondestructive testing for susceptibility, and determination of the mode of action of dantrolene.

Acknowledgment

This chapter is a consolidation of two chapters in the 8th edition, Chapter 42, Neuromuscular Disorders and other Genetic Disorders and Chapter 43, Malignant Hyperthermia and Muscle-Related Disorders. The editors, publisher, and the returning authors, would like to thank the following authors: Aranya Bagchi, Richa Saxena, and Diptiman Bose for their contributions to the prior edition of this work. It has served as the foundation for the current.
